Model-based extrapolation is always tricky, but especially so when the models are more complex. Consider much of macroeconomics. Models of a given economic system are developed from theory and past findings, and changes in parameter values are introduced to see how the system reacts to this perturbation. This is basically an extrapolation exercise to discover what would happen if some details of the economic system were not as they actually are. Can we extrapolate from what we think we know, in order to learn what would happen under novel circumstances? The validity of any extrapolation depends on the model being correctly specified with respect to the variables included, the relationships postulated between them, and the strengths of these relationships. Be wrong about any of these assumptions and any conclusions about the effects of the novel perturbation will be biased to some unknown extent. The assumption that the model is complete and accurate is difficult to test, though crucial to the credibility of the results (Glymour et al., 1987). Still, the creation of valid multivariate models of causal interdependency is another major goal of science, and it is not difficult to see why. It promises the extrapolation of results beyond whatever circumstances were studied in the past.

Conclusion

In the behavioral and social sciences at the beginning of the twenty-first century, theory and practice are most developed when individuals or households are sampled to describe a human population. Here, best practice requires randomly sampling units from the population. Theory and practice are also well developed for generalizing from a measure to an abstract construct or from an experimental treatment to a more general causal agent. Here, best practice requires an explicit theory of construct validity that necessarily invokes proximal similarity, but preferably also the heterogeneity of irrelevancies, discriminant validity, and causal explanation. However, the purposive selection and theory-linked methods needed for construct validation are not as formally well supported as random selection is. Theory and practice are even less developed for generalizing to settings and historical time periods and for identifying the conditions under which a causal relationship holds. However, various deliberate sampling and replication strategies are relevant here, including meta-analysis. At their best, such strategies borrow much of the logic underpinning sophisticated construct validation. Least well developed are theory and practice for extrapolating results to nonstudied circumstances. But even here, understanding causal explanatory processes can permit re-creation of the same causal forces in novel settings. Also, there are now decades of research and reflection about using animals to extrapolate to humans and about using the laboratory to extrapolate to other social settings. In addition, substantive modeling is sometimes used to examine what would happen to a system if one or more of its parameters were changed. Of all the methods examined, only random sampling provides an impeccable formal rationale for generalization. But its reach is, alas, limited. It is a great irony that the best formal method for generalization in the behavioral and social sciences can be used for only a small part of the generalization tasks that practicing social scientists routinely face. Given this, practicing social scientists and theorists of method reflecting on these practices have cobbled together more complex methods of generalization that depend more heavily on substantive theory, purposive sampling, heterogeneity of irrelevancies and demonstrated replication and the identification of causal contingencies.

Generalized Linear Mixed Models

Charles E McCulloch and John M Neuhaus, University of California, San Francisco, San Francisco, CA, USA

Abstract

This article provides an overview of generalized linear mixed models (GLMMs), how they are fit to data, and the inferences possible when using them. GLMMs are a class of statistical models that handle a wide variety of distributions for the outcome, accommodate nonlinear models, and model correlated data. As regression methods, they are not only capable of estimation and testing of covariate effects but also can be used to draw inferences about correlation structures in the data and are able to calculate predicted values that take into account not only covariates but also observed outcomes. We briefly describe software available for fitting GLMMs.

Introduction

Research questions often focus on analysis of change over time and use longitudinal and repeated measures designs. For example, in the Sacramento Area Latino Study of Aging (SALSA), a cohort of elderly Latinos was recruited to study, among other goals, the influence of diabetes on cognitive decline (Wu et al., 2003). In SALSA, cognitive functioning was assessed at baseline and in annual follow-ups by the Modified Mini-Mental State Examination (3MSE), which measures cognitive ability on a numeric scale that ranges from 0 (the worst) to 100. If the study was a cross-sectional study, then we might model 3MSE score as a function of diabetes status and other covariates (e.g., age, gender, hypertension, education) using linear regression. However, linear regression assumes that the outcomes are independent so that the method would not be able to accommodate the repeated measurements over time and the resulting correlated outcomes within a person.

Furthermore, the values of 3MSE are often dichotomized into cognitively impaired or not, with values under 79 indicating cognitive impairment. While dichotomizing a numeric outcome engenders a loss of information, it is sometimes an advantage to simplify clinical interpretations. With a cross-sectional study, we might use logistic regression to model cognitive impairment (Yes/No) as a function of the same predictors of diabetes status, age, gender, hypertension, and education. But, again, as with linear regression, this would not be appropriate with repeated, correlated outcome measures. Another feature of this design is the fact that some of the predictors (e.g., gender) do not vary with the repeated measurements over time and are measured at the person level, whereas other will vary, for example, hypertension.

In this article, we describe a flexible class of statistical models that are capable of accommodating correlated outcome data of a variety of different outcome types (e.g., numeric versus binary) and also predictors that are measured at different 'levels' in the study (e.g., at the person or within-person level). These are known as *generalized linear mixed models* (GLMMs) with the various components of the name being informative. The term 'generalized' indicates that a variety of distributional assumptions are possible (Normal or Gaussian, binomial, Poisson, etc.) to handle outcomes of different types. The term 'linear' indicates that the predictors enter the model together as a linear combination, just as in a linear regression where the effects of predictors enter the statistical model through an equation of the form,

$$\beta_0 + \beta_D DIAB + \beta_A AGE + \beta_E EDUC + \beta_G GEND \qquad [1]$$

Finally, the term 'mixed' indicates the method by which correlated outcomes are modeled as correlated, which we describe in more detail below.

We begin by describing how GLMMs accommodate correlated data and then formally define the class of models that comprise GLMMs. In the Section Types of Inferences Possible from GLMMs, we list the statistical inferences possible using GLMMs and then (in the Section Fitting and Inferential Methods) how they are fit to data. The Section Best Prediction discusses a unique feature of GLMMs, namely, prediction, and we close with brief sections on diagnostics and missing data.

Accommodating Correlation in GLMMs

The key idea in GLMMs is to incorporate correlation by modeling one or more of the predictors as random. Predictors that are not random are called fixed and because the model includes both fixed and random predictors it is described as a 'mixed' model. The impact of including a random predictor is easiest to describe in the context of a linear model, so we consider a simple one using the SALSA investigation.

Suppose we wish to create a model for a person's 3MSE score as a function of their diabetes status at the current visit, with M_{it} denoting the 3MSE for person i at time t, a simple model would be

$$M_{it} = \beta_0 + P_i + \beta_D DIAB_{it} + \varepsilon_{it} \qquad [2]$$

where P_i is person effect and $DIAB_{it}$ is 1 if the person is diabetic at time t and 0 otherwise. Larger values of P_i will tend to lead to larger measurements on a person, allowing the model to capture the feature that some participants' 3MSE scores are consistently higher and others are consistently lower. In a longitudinal context, $\beta_0 + P_i$ would be a person-specific intercept, allowing individuals to start at different values. The ε_{it} is an error term with mean 0 and with a variance we will denote by σ_ε^2.

To make statistical inferences from our experiment, we will need to assume that the people in the study are a random sample from some population of people, real or hypothetical.

Consequently, the person effects are necessarily a random sample of the person effects from that population, which has a distribution in the population with a variance, we will denote by σ_P^2. This simple idea, of regarding the person effects as random, introduces a covariance between outcomes (say outcome at time t and outcome at time s) within a person.

$$\begin{aligned}\text{cov}\,(M_{it}, M_{is}) &= \text{cov}\,(\beta_0 + P_i + \beta_D DIAB_{it} + \varepsilon_{it}, \\ &\qquad \beta_0 + P_i + \beta_D DIAB_{is} + \varepsilon_{is}) \\ &= \text{cov}\,(P_i + \varepsilon_{it}, P_i + \varepsilon_{is}) \qquad [3] \\ &= \text{cov}\,(P_i, P_i) \equiv \text{var}\,(P_i) \qquad [4] \\ &= \sigma_P^2\end{aligned}$$

In the above, equality [3] holds because the omitted terms are fixed constants and equality [4] holds under the assumption that the error terms are uncorrelated with each other (and uncorrelated with the P_i). In a similar fashion, it is straightforward to calculate the variance of M_{it} or M_{is}, both of which are equal to $\sigma_P^2 + \sigma_\varepsilon^2$, so that their standard deviation is $\sqrt{\sigma_P^2 + \sigma_\varepsilon^2}$. With these facts in hand the correlation between two measurements taken on the same person would be

$$\begin{aligned}corr(M_{it}, M_{is}) &= \frac{\sigma_P^2}{\sqrt{\sigma_P^2 + \sigma_\varepsilon^2}\sqrt{\sigma_P^2 + \sigma_\varepsilon^2}} \\ &= \frac{\sigma_P^2}{\sigma_P^2 + \sigma_\varepsilon^2}\end{aligned} \qquad [5]$$

the well-known intraclass correlation coefficient.

This simple model with only random intercepts generates equal correlation between two outcomes on the same person. This will not be sufficiently flexible for many situations, but can easily be added upon. For example, SALSA recruited participants across a number of census tracts, all of which had high percentages of Latinos. It could well be that observations on individuals within census tracts tend to be systematically higher or lower than other census tracts, perhaps because of unmeasured characteristics. Letting M_{cit} denote the 3MSE measurement at time t for participant i in census tract c, an elaboration of eqn [2] would be

$$M_{cit} = \beta_0 + T_c + P_{ci} + \beta_D DIAB_{cit} + \varepsilon_{cit} \qquad [6]$$

where T_c is a census tract effect. If we assume that the T_c are random effects then calculations similar to those in eqns [4] and [5] give the following correlations for, respectively, outcomes measured on the same person (and in the same census tract) at different times and different people in the same census tract (at any time):

$$\begin{aligned}corr(M_{cit}, M_{cis}) &= \frac{\sigma_T^2 + \sigma_P^2}{\sigma_T^2 + \sigma_P^2 + \sigma_\varepsilon^2} \\ corr(M_{cit}, M_{cjs}) &= \frac{\sigma_T^2}{\sigma_T^2 + \sigma_P^2 + \sigma_\varepsilon^2}\end{aligned} \qquad [7]$$

Model [2] also has the feature that correlations between measurements taken on the same person are the same irrespective of how far apart they are in time, which might not be realistic. There are also logical extensions of this model that are more realistic in longitudinal studies. For example, suppose we were interested in a model to address whether diabetes status at baseline was predictive of decline in cognitive functioning or not. Since a time effect measures overall decline in cognitive functioning, to capture the concept of decline depending on diabetes status we would incorporate a diabetes status by time interaction.

Because some participants will maintain cognitive function with age while others will decline, we will need to allow not only person-specific intercepts but also person-specific slopes. Figure 1 shows the values of 3MSE plotted versus age for

Figure 1 3MSE values by age for nine SALSA participants showing linear fits and actual values.

a selected subset of the SALSA participants, making it clear the need for both person-specific intercepts and slopes.

Here is a model that includes person-specific intercepts and slopes, as well as the diabetes and diabetes by time interaction:

$$M_{it} = (\beta_0 + P_i) + (\beta_T + PT_i)TIME_{it} + \beta_D DIAB_{i0} + \beta_{DT} DIAB_{i0} \times TIME_{it} + \varepsilon_{it} \quad [8]$$

In this model, $\beta_0 + P_i$ is the person-specific intercept and $\beta_T + PT_i$ is the person-specific decline over time. By the same random sampling argument above, the PT_i form a random sample from a population of person-specific slopes with some variance. That variance will be different from the variance of P_i (since they are measured on different scales), and it is quite possible that P_i and PT_i are correlated. For example, participants who started with low values (negative P_i) might decline more rapidly.

As illustrated in the examples above, the specification of a GLMM involves four basic steps:

1. Specify the distribution of the outcome Y. This is the distribution for fixed values of the predictors and conditional on the random effects. For example, in the SALSA examples we might use a normal distribution for 3MSE and a Bernoulli distribution for cognitive impairment (3MSE < 79).
2. Specify the predictors to be included in the model. As noted in eqn [1], these will enter the model in the form of a linear combination. This is typically called the *linear predictor* and is denoted by η. In more generic notation, it would be defined as $\eta = \beta_0 + \beta_1 x_1 + \cdots + \beta_p x_p$, where the βs are regression parameters to be estimated from the data and x_k are the predictors.
3. Specify which function of the mean, $\mu \equiv \mathrm{E}[Y|x]$, is equal to the linear predictor. In a GLMM, this is of the form $g(\mu) = \eta$, where g is a known monotonic function, called the *link* function. For example, with a binary outcome, we might specify g as the logit function, i.e., $g(\mu) = \log\left(\frac{\mu}{1-\mu}\right)$.
4. Declare one or more of the categorical predictors to be random factor(s) by assigning a distribution to the effects associated with the levels of that factor.

The Model

We are now in a position to more formally define a GLMM using the following notation. For the ith observation, let Y_i denote the outcome and let μ_i be the mean of Y_i, conditional on the random effects. Further, let $\mathbf{x}_i$ be the vector of fixed effect (nonrandom) predictors, $\mathbf{z}_i$ be the model matrix for the random effects, $g(\cdot)$ be the link function, β be the regression coefficients, and $\mathbf{u}$ be the vector of random effects. Our GLMM is then

$$\begin{aligned} Y_i|\mathbf{u} &\sim \text{indep. } f_Y(Y_i|\mathbf{u}) \\ g(\mu_i) &= \mathbf{x}_i'\beta + \mathbf{z}_i'\mathbf{u} \\ \mathbf{u} &\sim f_u(\mathbf{u}) \end{aligned} \quad [9]$$

where f_Y and f_u are, respectively, the density functions of Y and $\mathbf{u}$.

Using the cognitive impairment example above to illustrate the definition of a GLMM, define C_{it} to be 1 if the 3MSE score is less than 79 and 0 otherwise so that the outcome is binary. We therefore could use a logit link and might include random intercepts (u_{0i}) and random slopes over time (u_{1i}) and assume that the random effects follow a normal distribution:

$$C_{it}|\mathbf{u}_i \sim \text{indep. Bernoulli}(p_{it},), i = 1, \ldots, m; t = 1, \ldots, n_i$$

$$\log[p_{it}/(1-p_{it})] = (\beta_0 + u_{0i}) + (\beta_1 + u_{1i})TIME_{it} \quad [10]$$

$$\text{or } p_{it} = 1/[1 + \exp\{-[(\beta_0 + u_{0i}) + (\beta_1 + u_{1i})TIME_{it}]\}]$$

$$\mathbf{u}_i \sim \text{indep. } \mathcal{N}(\mathbf{0}, \Sigma_{\mathbf{u}})$$

where the joint distribution of $\mathbf{u}_i = (u_{0i}\, u_{1i})'$ is bivariate normal.

Types of Inferences Possible from GLMMs

GLMMS are based on generalized linear models, which are nonlinear regression models. So GLMMs allow the usual inferential goals that regression models are used for. They can be used to test the association of an outcome with a predictor, to quantify the degree of association, or to estimate the mean value of the outcome for given values of the predictors. For example, in SALSA there was an interest for testing if diabetes was related to cognitive impairment and in quantifying the strength of the association. Another possible inferential goal would be to predict the chance of cognitive impairment for subgroups of the participants, e.g., diabetic women over the age of 60.

There are, however, two types of inferences that are possible from GLMMs that are not possible from generalized linear models, both related to the inclusion of random effects in the model [9]. First, we can analyze features of the random effects distribution. For example, in model [10], the variance of u_{2i} (the lower right element of $\mathbf{\Sigma}_{\mathrm{u}}$) measures the variability in the cognitive impairment declines across different participants, so testing the null hypothesis of $H_0 : \sigma^2_{u2} = 0$ tests the hypothesis that all participants decline at the same rate. This might be useful as a precursor to identifying if there were some participants with 'healthy aging,' i.e., not losing cognitive ability, whereas others were declining.

Second, GLMMs can be used to obtain predicted values of the random effects, thereby allowing person-specific predictions of, in the SALSA example, declines in cognitive ability over time. These predicted values are based not only on the measured characteristics (e.g., female, diabetic, over the age of 60) but also on the observed values of the outcome for that individual.

Fitting and Inferential Methods

The fitting of GLMMs to data is computationally challenging and a number of approaches have been proposed. By far the most common method and a method implemented in many software packages is maximum likelihood based on numeric evaluation of the likelihood.

Maximum Likelihood

Maximum likelihood or minor variations of maximum likelihood, such as restricted maximum likelihood, are standard methods of estimation for linear mixed models and generalized linear models (e.g., logistic regression), the building blocks of GLMMs. It is, therefore, unsurprising that maximum likelihood is regularly used for GLMMs. Maximum likelihood (ML) is attractive because of features associated with the method in general, namely, the following:

Under mild conditions:

- ML estimators are asymptotically unbiased and normally distributed.
- The standard errors can be approximated using second derivatives of the log likelihood.
- ML estimators are asymptotically efficient, i.e., have the smallest variance.
- Hypothesis testing can be conducted with likelihood ratio, score, or Wald tests.

With ML estimators being asymptotically unbiased and normally distributed, it is straightforward to derive Wald tests based on large sample normality or chi-square distributions.

An exception in GLMMs to the usual large-sample distributions for hypothesis testing is when testing the null hypothesis that one (or more) of the variances of the random effects is zero (as noted above in testing for no variation in cognitive decline) using a likelihood ratio test. In such a case, the likelihood ratio test does not have the usual large sample chi-square distribution under the null hypothesis. Its large sample null distribution is a mixture of chi-square distributions (Self and Liang, 1987) and is sometimes called a $\overline{\chi}^2$ distribution. For a model with a single random effect, the use of the $\overline{\chi}^2$ test is straightforward and is achieved by halving the p-value from a standard, 1 degree of freedom chi-square test or, equivalently, by referring the test statistic to a chi-square distribution with the cutoff based on 2α. This is essentially the same as converting the p-value from a two-sided Z- or t-test to a one-sided hypothesis test.

Computing Maximum Likelihood Estimates

While the use of maximum likelihood for GLMMs is straightforward in concept, it is computationally difficult. This is because the model is specified conditional on the random effects, and calculation of the likelihood requires integrating out the random effects to obtain the marginal likelihood. Consider a simple logistic mixed model with a single, time-invariant predictor (x_i) and with only random intercepts that follow a normal distribution. Further assume that, conditional on the random intercepts, the outcomes, Y_{it}, are independent. The contribution to the likelihood from the data associated with the ith person is

$$\begin{aligned} \mathrm{P}\{\mathbf{Y}_i = y_i|\mathbf{x}_i\} &= \int \mathrm{P}\{\mathbf{Y}_i = y_i|u_i = u, \mathbf{x}_i\} f_{ui}(u)du \\ &= \int \prod_{t=1}^{n_i} \mathrm{P}\{Y_{it} = y_{it}|u_i = u, x_i\} f_{ui}(u)du \end{aligned} \quad [11]$$

$$\begin{aligned} &= \int \prod_{t=1}^{n_i} p_{it}^{y_{it}} (1-p_{it})^{1-y_{it}} f_{ui}(u)du \\ &= \int \prod_{t=1}^{n_i} p_i^{y_{it}} (1-p_i)^{1-y_{it}} f_{ui}(u)du \qquad [12] \\ &= \int \left(\frac{p_i}{1-p_i}\right)^{y_{i\cdot}} (1-p_i)^{n_i} f_{ui}(u)du \\ &= \int_{-\infty}^{\infty} \frac{e^{y_{i\cdot}(\beta_0+\beta_1 x_i+u)}}{(1+e^{\beta_0+\beta_1 x_i+u})^{n_i}} \frac{e^{-u^2/2\sigma_u^2}}{\sqrt{2\pi\sigma_u^2}} du \qquad [13] \end{aligned}$$

with $y_{i\cdot} = \sum_t y_{it}$ and the simplification in eqn [12] and the line below it occurring because x is constant within a person and therefore $p_{it} = p_i$. Because eqn [13] cannot be evaluated in closed form neither can be the likelihood, much less maximized in closed form. So even for this very simple logistic regression model with a single predictor and random intercepts, evaluation of the likelihood requires numerical methods.

Numerical Computations for Maximum Likelihood

Evaluation of the value of the likelihood for GLMMs is typically achieved either by numerical integration or other forms of numerical approximation. A typical method is to use an approach called Gauss–Hermite quadrature, which is appropriate for normally distributed random effects and numerically evaluates the integrals, such as those in eqn [11], with a quickly computed summation. The accuracy of the approximation of Gauss–Hermite quadrature can be improved by choosing more 'quadrature points,' albeit at the cost of making the computations slower. To improve the approximations, the integrands are often centered and scaled to make sure that the calculations are used in the region where eqn [11] has the most nonzero contribution. To speed computation some algorithms adaptively choose the number of quadrature points to be as small as possible but still achieve acceptable accuracy. In our experience using Gauss–Hermite quadrature in applications and when using centered and scaled algorithms we have found that using 20 quadrature points usually gives a good degree of approximation. For numerically difficult problems we have encountered inaccurate fits when using values less than 10.

The steps outlined above are merely to calculate the likelihood. However, to obtain model fits, the likelihood still has to be maximized. To avoid calculation of derivatives (which also cannot be evaluated in closed form and require integral approximations), quasi–Newton algorithms (with derivatives approximated with differences) or derivative-free maximization methods are often used to maximize the numerically evaluated likelihoods. Standard errors or predicted values require even more involved numerical approximations.

Other Numerical Approximations

Because numerical integration of the likelihood can sometimes be very slow or even infeasible, especially when dealing with multiple random effects, other approaches have been considered. One is the so-called *Laplace approximation* (e.g., Wolfinger, 1993; Raudenbush et al., 2000), which is an alternative method

of approximating the integrals in eqn [11]. It is also mainly applicable when the random effects are normally distributed.

Another approach to fitting GLMMs is motivated by adapting the most common fitting method for generalized linear models, which is to fit models by maximizing the log of the *quasi-likelihood*. This quasi-likelihood approach is attractive because it does not explicitly make distributional assumptions, but instead is based only on the assumed relationship of variance to mean. But integrating out the random effects from the quasi-likelihood is no easier than integrating them out of the true likelihood, so numerical approximations are again needed.

This leads to 'penalized quasi-likelihood,' which consists of a quasi-likelihood contribution with an added penalty term of $\sum_i u_i^2/2\sigma_u^2$. The penalty term can be motivated either as arising from assuming that the random effects follow a normal distribution or simply as a device to keep the individual random effects u_i relatively 'small.'

Because these methods do not have direct theoretical justification like maximum likelihood, their performance needs to be quantified with separate investigations, even for large samples. In general, these methods are considerably faster than numerical maximum likelihood but can give estimators with higher bias. Pinheiro and Chao (2006), via simulation, and Joe (2008), via evaluation of the asymptotic limit of maximizers of the Laplace-approximated likelihood show that the Laplace approximation approach can work well in some cases, but suffers from some degree of bias, especially with binary outcomes and with small cluster sizes. To address this bias some authors have explored using higher order Laplace approximations (Raudenbush et al., 2000).

Penalized quasi-likelihood methods seem to have somewhat more bias than Laplace methods. While they generally give acceptable answers when the outcome distribution is close to normal they can fail when the distributions are far from normal, e.g., binary or Poisson with small mean counts (Breslow and Clayton, 1993; Breslow and Lin, 1995; Lin and Breslow, 1996; Neuhaus and Segal, 1997). If outcomes are approximately normal, use of linear mixed models and reliance on their robustness (see below) is an option. So the very situation in which GLMMs are arguably most needed is when quasi-likelihood and Laplace methods work less well.

Bayesian Methods

GLMMs can also be modeled using Bayesian methods instead of frequentist approaches based on likelihood inference. Bayesian inference would also begin with a GLMM such as eqn [9]. As usual, a Bayesian approach would need to make further assumptions about the distributions for the parameters themselves, such as β, rather than regarding them as fixed, unknown constants, as does the likelihood approach. So, in a sense, all parameters are random effects under the Bayesian paradigm.

Some have argued that random effects models are inherently Bayesian because they assume a distribution for the parameters, but we feel differently. In the mixed model approach, random effects are modeling tangible distributions, while assuming distributions (in the Bayesian approach) for parameters does not. In the SALSA example, the random effect distribution represents the variation in person-specific quantities from the mixed model across the population of people. That is quite different than assuming a distribution for the effect of diabetes, β_D, from, say, eqn [6].

Software

In recent years, a number of software packages have incorporated and improved the analysis methods available for GLMMs. For example, Stata, SAS, SPSS, and R all have routines that can fit GLMMs. In Stata, the main routine is meglm (for mixed-effects generalized linear models) with many other more specialized mixed effects command, e.g., xtologit for ordinal logit models with random effects. In SAS, the glimmix and nlmixed procedures fit GLMMs. In SPSS, GLMMs are fit with genlinmixed, available in their Advanced Statistics Module and accessible through the menuing system under Analyze > Mixed Models. R has a number of routines including those in lme4, glmmML, and glmmPQL. The defaults and options for the methods for fitting GLMMs (e.g., maximum likelihood versus Laplace versus penalized quasi-likelihood) vary widely by package. In light of the possible bias with different fitting methods (see Section Other Numerical Approximations), it is prudent for the user to be clear on which method is being used.

Best Prediction

As noted in Section Types of Inferences Possible from GLMMs, an advantage of using GLMMs is the ability to derive person-specific predictions based not only on the covariates but also on the outcomes observed for that person. For example, in SALSA we could derive predicted values for the person-specific intercepts and slopes and thereby derive predicted trajectories of cognitive change. Working from the basic GLMM model [9], we would need an estimated value for $\mathbf{x}_i'\beta + \mathbf{z}_i'\mathbf{u}$. Maximum likelihood or another fitting method will yield estimates of β and the parameters in the random effects distribution, $f_u(u)$, but not estimated values of the $\mathbf{u}_i$. This is because the marginal likelihood is integrated over the random effects and they do not appear in the likelihood. So a different approach is needed to find estimates of the $\mathbf{u}_i$.

Most approaches calculate estimates derived to have good performance in prediction. The most common approach is to use estimators that minimize the squared prediction error, namely, to choose a predictor, $\tilde{u}$, of the random effect u according to

$$\tilde{u} \text{ minimizes } \mathrm{E}\left[(\tilde{u}-u)^2\right]. \qquad [14]$$

Simple mathematics shows that the minimizer is given by $\tilde{u} = \mathrm{E}[u|\mathbf{Y}]$. Intuitively this makes sense because the predicted value is chosen as the average of the random effects consistent with the observed data.

In general, the quantity $\mathrm{E}[u|\mathbf{Y}]$ depends on the unknown parameters β, as well as the parameters in the random effects distribution. So, in practice, the estimated values (e.g., from a maximum likelihood fit) are inserted in place of the true values. Predicted values are then calculated by using $\mathbf{x}_i'\widehat{\beta} + \mathbf{z}_i'\tilde{\mathbf{u}}$ in the model eqn [9].

The predicted values, while not necessarily calculated using Bayesian methods, are nevertheless closely related to Bayesian

quantities, as $E[u|\mathbf{Y}]$ is the posterior mean of the random effects. The predicted values are also sometimes characterized as 'shrinkage' estimators since they are closer to zero than estimates that would be obtained by treating the random effect as a fixed effect and deriving separate estimates for each level of the effect.

Diagnostics

Specification of a GLMM involves the steps outlined in Section The Model. Choices involve specifying the distribution of the outcome as well as the distribution of the random effects and choosing a link function.

Distribution of *Y*

As with modeling outcomes that are not correlated, choosing the distribution for the outcome is often challenging. When the data are binary the choice is easy, since only the Bernoulli distribution can be correct. But for numeric or count data, there can be little information to guide the choice. For example, consider an outcome such as number of emergency room visits during a year. On one hand it is a count variable, so the temptation might be to model it as following a Poisson distribution. In our experience, it almost certainly will have a distribution with a variance that is much larger than that required by a Poisson distribution. Thus, conducting an analysis assuming that the Poisson distribution holds could easily lead to misleading inferences with standard errors being too small, confidence intervals too narrow, as well as *p*-values that are falsely small.

With linear regression models a common diagnostic tool is the residual plot, with analysts considering histograms, quantile plots and scatterplots of residuals versus predictors and versus predicted values. Unfortunately, residual plots for GLMMs are not as easy to interpret. Consider the relatively simple case of a linear mixed model, for which the marginal mean is $\mathbf{x}_i'\beta$ but the mean conditional on the random effects is $\mathbf{x}_i'\beta + \mathbf{z}_i'\mathbf{u}$. So we can define two types of residuals, marginal ($r_{i,m}$) or conditional ($r_{i,c}$):

$$r_{i,m} = y_i - \mathbf{x}_i'\widehat{\beta} \quad \text{or} \qquad [15]$$

$$r_{i,c} = y_i - \left(\mathbf{x}_i'\widehat{\beta} + \mathbf{z}_i'\tilde{\mathbf{u}}\right) \qquad [16]$$

where $\tilde{\mathbf{u}}$ is the predicted value of $\mathbf{u}$. These are useful for identifying some basic issues: extreme nonnormality of the errors, outliers and nonlinearities (when plotted versus a predictor). However, they fail to have some of the other common features of residuals for linear regression models, making interpretation less straightforward. For example, they are not homoscedastic and are correlated with the predicted values. For nonnormal distributions and for nonlinear link functions, residual-based diagnostics tend to be of even less use. Even so, some rough guidance can be gained by plotting residuals versus predicted values to get a crude indication of the relationship of the standard deviation to the mean, which may inform a distributional choice.

A different tactic is to take a model-based approach to diagnosing specification of the distribution by trying more general or alternate distributions. For example, the negative binomial distribution contains the Poisson as a special case. So by fitting a negative binomial model and comparing it to a Poisson model, one can judge whether the extra flexibility allowed by the negative binomial model is needed (Booth et al., 2003). When more general distributional specifications are not available, one can try alternate distributions and rough comparisons can be made on the basis of the log likelihood values for the different fits. GLMM routines available in software allow a wide variety of distributional choices and procedures such as SAS's nlmixed even allows user-specified distributions.

The linear mixed model does have some favorable robustness properties (Jacqmin-Gadda et al., 2007), so it may be attractive to use linear mixed models for outcomes that are approximately normally distributed or can be transformed to be approximately normally distributed. Even when the outcome is nonnormally distributed, maximum likelihood estimators in linear mixed models are consistent (Richardson and Welsh, 1994).

Distribution of Random Effects

We (McCulloch and Neuhaus, 2011a) wrote a review of the performance of fitting GLMMs when various assumptions about the random effects distribution are violated, focusing on models with random intercepts, and have some additional work on random intercept and slope models (Neuhaus et al., 2013). In many situations, using maximum likelihood fitting with an assumed normal distribution for the random effects (which is what most software assumes) was highly robust. There were, however, two main violations of assumptions that can cause bias: (1) an association of the mean of the random effects distribution with a predictor (Neuhaus and McCulloch, 2006) and (2) an association of the variance of the random effects distribution with a predictor (Heagerty and Kurland, 2001).

An extensive literature exists on the effect of misspecifying the *shape* of the random effects distribution, for example, modeling it as normal when it is, in fact, skewed. The general conclusion is that statistical inferences (with few exceptions) are highly robust to this type of misspecification and that fits assuming normally distributed random effects perform quite well. Robustness extends to estimation of covariate effects, estimation of the random effects variance, and the mean square error of prediction of the realized value of random effects. Particularly robust in the face of a misspecified random intercepts distribution was estimation of the effects of covariates that mainly vary within clusters. This is especially important because evaluation of such covariates is a primary reason for conducting longitudinal or clustered data studies.

Minor exceptions to robustness to shape misspecification are estimation of the parameters that have associated random effects that are badly misspecified (e.g., the intercept when the random intercept distribution is badly misspecified). Also, although the mean square error of prediction of random effects is robust to misspecification, the distribution of the predicted values takes on the shape of the *assumed* form of the random effects distribution and thus the actual predicted values can be affected.

Between and within Covariate Decompositions

It is useful to distinguish three covariate types in clustered and longitudinal data: (1) between-cluster covariates, such as baseline covariates in a longitudinal study, that take the same value for all units in the cluster; (2) purely within-cluster covariates, such as the time variable in a longitudinal study with no missing data, that take different values for every unit in a cluster; and (3) within-cluster covariates such as subject age in the SALSA study that vary both within- and between-clusters. For both substantive and statistical reasons, it is useful to decompose covariates of the third type into between- and purely within-cluster components. In particular, motivated by the form covariates take on in conditional likelihood approaches (Neuhaus and Kalbfleisch, 1998), it is useful to decompose a covariate such as age in the SALSA study, AGE_{it}, into a between-cluster component $\overline{AGE}_i = (1/n_i)\sum_{t=1}^{n_i} AGE_{it}$ and a within-cluster component $AGE_{it} - \overline{AGE}_i$.

Covariate decomposition methods are useful statistically because they can remove confounding at the cluster level (Neuhaus and McCulloch, 2006) and because they focus interest on within-cluster effects which are robust to many forms of model misspecification (McCulloch and Neuhaus, 2011b). Comparison of the between- and within-covariate effects can therefore serve as a diagnostic method. Covariate decomposition methods apply generally to noncanonical link functions and multiple random effects and extend conditional likelihood like methods to these more general settings.

Social science investigators find it useful to separate covariate effects of individuals from those related to a collection of individuals such as a neighborhood and to allow these effects to differ (Enders, 2013). In the social science literature, the differing covariate effects are known as contextual effects and one could estimate them using the covariate decomposition methods above.

Missing Data

Missing data are ubiquitous in practice. People drop out of studies and refuse to answer some questions, or data values are out of range and need to be dropped. Software typically deals with missing data by dropping the observation if it is missing the outcome or any of the covariates, called a *complete case analysis*. This can be inefficient (when there is a patchwork of missing data) and can lead to bias, because data are often missing because of reasons related to the outcome being studied. For example, people experiencing cognitive impairment may be less likely to come in for visits.

The approach to dealing with missing data depends crucially on whether the outcomes are missing (perhaps along with all the covariates, such as when a person drops out of a study) or some of the predictors are missing. When predictors are missing, the most common method is *multiple imputation*. In multiple imputation, predicted values of the missing data are filled in using both the outcomes and predictors that are present. This requires building a model for the missing data as a function of the present data. This prediction is done with noise (to reflect the uncertainty involved in filling in the data) and is done multiple times so as to be able to assess standard errors and calculate confidence intervals and *p*-values while properly accounting for the uncertainty in missing data.

When it is primarily the outcomes that are missing, multiple imputation can still be used. However, simply by using maximum likelihood fits to the data gives considerable protection against missing data, and will often give nearly unbiased results (Laird, 1988). This is easier than multiple imputation because no prediction equations for the missing data need to be derived.

The maximum likelihood and multiple imputation strategies for missing data described above work under the technical assumption that the data are 'missing at random,' detailed discussion of which is beyond the scope of this article. For an applied discussion on missing data methods, see Chapter 11 of Vittinghoff et al. (2012); for a more technical discussion, see Little and Rubin (2002).

Summary

Our goal in this article was to give a brief overview of GLMMs, how they are fit to data, and the inferences possible when using them. The hallmark features of GLMMs are the ability, within a single class of statistical models, to handle a wide variety of distributions for the outcome, accommodate nonlinear models, and model correlated data. As regression methods, they are capable of estimation and testing of covariate effects. But they go beyond nonlinear regression modeling by being able to accommodate correlated data, draw inferences about correlation structures in the data and by being able to calculate predicted values that take into account not only covariates, but also observed outcomes. Software for fitting GLMMs is widely available, though care should be taken with which fitting method is being used since some of the methods can give biased answers for high nonnormally distributed outcomes.

Generation in Anthropology

Sarah Lamb, Brandeis University, Waltham, MA, USA

Abstract

Generation has been a productive lens through which to study many facets of social–cultural life in anthropology. The concept of generation has been used by anthropologists to explain social change over time, to examine the ways people organize and envision intergenerational ties within the family, to explore principles of social organization beyond the family, and to identify differences among members of a society.

The concept of generation has been used by anthropologists to explain social change over time, to identify differences among members of a society, and to examine the ways people across cultures organize and envision family relationships, the life course, and the social-moral order. Generation also figures into the concept of culture central to anthropology: Anthropologists define culture as 'transgenerational,' transmitted from one generation to the next, at the same time that it is open to creative revision and change.

The term generation has two primary meanings. In one of its senses, generation refers to a group of people who are living through a time period together and participate in some kind of shared identity, practices, and beliefs. Generation is also used by anthropologists in its more genealogical, kinship-related sense, to refer to the relationship between parents and their children, these children and their children, and so on, and/or to forms of prestige and identity tied to one's position in such a system of kinship descent. Using one or both of these senses of the term, anthropological interest in generation has focused on four primary topics, pertaining to understandings of social change, of family moral systems and elder care, of social organization beyond the family, and of forms of identity and inequality. This article will look at each approach in turn.

Generation and Social Change

Generation has long been viewed as a lens through which to understand and imagine social change, both in the kinds of popular discourses studied by anthropologists and in scholarly models within anthropology and the related social sciences. Nineteenth-century social theorist August Comte located the impetus for social change in the younger generation, suggesting that increases in life span would slow down the tempo of social progress, because the conservative, restrictive influence of the older generation would operate for a longer time, should they live longer, thus thwarting the 'innovating instinct that distinguishes the young' (1974[1855]: 518). Karl Mannheim in his 1920s classic essay, *The Problem of Generations*, went on to speculate that cultural transformation comes about precisely through the continuous emergence of new generations: As each new generation comes into 'fresh contact' with its social and cultural heritage, it remodels what is found (1952[1927]: 293). French anthropologist, sociologist, and philosopher Pierre Bourdieu likewise implicitly thinks about the social change in generational terms when developing his influential theory of the habitus. Bourdieu writes of how the habitus of people born of different generations will often be in conflict, because their habitus have been produced under different circumstances:

> This is why generation conflicts oppose not age-classes separated by natural properties, but habitus which have been produced by different modes of generation, that is, by conditions of existence which, in imposing different definitions of the impossible, the possible, and the probable, cause one group to experience as natural or reasonable practices or aspirations which another group finds unthinkable or scandalous, and vice versa. (1977: 78)

Anthropologist Meyer Fortes similarly muses that a generational model is an 'apt imagery by means of which to depict continuities and discontinuities in a community's social and cultural life over a stretch of time' (1984: 106). It is within the framework of the succession of generations, Fortes explains, that all people acquire their cultural heritage: "Mediated from earliest infancy by the natal family, the society readily takes on a generational form to the individual" (p. 106). The popular folk model of the 'generation gap' also envisions social change in generational terms, imagining the young generation moving forward, separated by a 'gap' from, the more static, 'old-fashioned' old.

Despite the enormous explanatory power given to generational change by both local people themselves and in classic social science texts, the concept of generation has never taken center stage in anthropological ethnography or theory. Yet over recent years, several anthropologists have claimed that generation is a key site through which to understand in particular the social processes associated with modernity and globalization (Cole and Durham, 2007; Cole, 2010; LiPuma, 2000). Edward LiPuma's ethnography examines the process of encompassment of the Maring of Highland New Guinea by colonialism, capitalism, and Christianity – "what is known as modernity" (2000: xi), and he argues that "there can be no theory of transformation without a theory and ethnography of generations, a concept often presupposed in anthropological discourse but rarely spoken about" (2000: xiii). LiPuma examines the period from roughly 1955 to 1980, when (1) the oldest generation (those generally over about age 60) could recall a life unfettered by foreign interventions, (2) the middle generation in power (aged 30s to mid 50s) had been brought up in a traditional world but lived now wholly in the

modern, and (3) the younger generation had never known a world untouched by missions and government and capitalism (p. 16). LiPuma contends that by examining the changing categories of knowledge and structures of desire across these generations, he is able to illuminate the broader dynamics of social-cultural transformation in Melanesia and beyond (p. 63), arguing that "an understanding of generations is essential to an account of… the creation of the modern" (p. 64).

In her ethnography of the coming of age of a generation of women in neoliberal Madagascar, Jennifer Cole (2010) examines "the ways new generations come to have a special force in social change" (p. 190). Her text foregrounds generation as a productive theoretical concept while cautioning that both popular and scholarly ways of interpreting generational change "offer a symbolic shorthand for understanding more complex dynamics" (p. 5). "This is never a mechanical, unreflexive matter of one cohort replacing another as some theories of generational change have implied," Cole reflects. "Rather, it is a highly imaginative undertaking in which people's desire to be good and valued, their culturally shaped dilemmas, and their visions for the future meet the broader forces of history and culture in unpredictable, uneven ways" (p. xii).

Because youth figures so prominently in how social change is imagined in both scholarly and colloquial discourses, it is perhaps not surprising that youth, more than any other age group, has been the focus of anthropological studies of generational change. A recent surge of work emphasizes the transformative impact of 'youth cultures' and 'youth agency' in the contemporary global era (Lamb, 2009: 15–16, 276, note 30). Yet one of the central arguments of Lamb's (2009) ethnography focusing on older people in India and abroad is that it is inadequate to think of the young as the only or perhaps even primary locus of social-cultural change. Lamb's data show that, even though they tend to be viewed by others and to view themselves as in many ways emblematic of 'tradition,' those of the senior generation are at the same time very often actively involved in fashioning new modes of life for themselves and their descendants.

The Cultural Construction of Intergenerational Ties

A second major body of anthropological work examines relations between generations of kin. Such work on the cultural shaping of intergenerational ties foregrounds generation in its genealogical sense as a descent relationship. Interest in intergenerational family relationships has existed since the beginnings of anthropology as a discipline, largely due to the analysis paid by anthropologists to kinship systems. Since about the 1970s, the majority of work on intergenerational ties has come out of the subfield of anthropology of aging, where one of the central research issues has surrounded the degree to which the elderly can expect to receive various forms of support from their younger relatives. Research on intergenerational ties, however, goes well beyond the (interesting and important) problem of how the elderly are cared for, to speak to broader conceptions about the nature of the family, the relationship among individuals, genders, families, the market and the state, and people's visions of the social-moral order.

Lamb (2000, 2009) examines such problems through a focus on West Bengal, India. She finds that Bengalis perceive intergenerational family relations to entail long-term bonds of reciprocal indebtedness extending throughout life and even after death. People widely believe that it is natural for adult children to provide care for their elderly parents, reconstruct relations with parents as ancestors after death, and ritually nourish these ancestors, as a means of repaying the tremendous 'debts' they owe their parents for producing and caring for them in infancy and childhood. What parents once gave their children to produce and raise them – such as a body in birth, food, material goods, money, a home, forms of love, the cleaning of urine and bowel movements – children are expected to provide in return for their parents years later in old age and after death. (Children, for instance, construct new spirit bodies for their parents as ancestors, parallel to the bodies parents create for their children in birth.) Other anthropologists have found that relationships of lifetime intergenerational reciprocity, conceptualized and practiced in varying ways, are not uncommon cross-culturally (Alber et al., 2008; Ikels, 2004; Sokolovsky, 2009).

The shaping of intergenerational ties speaks not only to aging and the family per se but also, frequently, to wider debates concerning the social, moral, and political conditions of a broader society and nation. Indian discourses, for instance, commonly present close, multigenerational families as signifying a 'good' and 'Indian' society; whereas disintegrating generational ties – the breakup of joint families, a rise in individualism, and the emergence of old-age homes – are held to be paradigmatic signs of an ambivalently valued modern, Westernizing, and globalizing era (Lamb, 2009). Similarly, people in Japan and China are reworking and debating the long-held principle of filial piety in the face of transitions such as population aging, the one-child policy in China, resistance on the part of daughters-in-law, and the younger generation's increasing desire for independence and generational equality (Ikels, 2004).

Anthropologists have thus found that the shaping of intergenerational ties is powerfully linked with surrounding cultural values. Andrei Simic (1983) suggests links between an American model of intergenerational relations and a broader cultural orientation toward self-fulfillment and individualism. Children in middle-class, Anglo-American households maintain their own rooms and possessions, and by about age 18 are expected to move out and live separately from their parents. "Though parents often extend financial aid to their children after they have left home," Simic observes, "it is almost always with the overt rationale of helping them get established as independent units, rather than creating a binding reciprocity of mutual dependence between the two generations" (p. 86). In later life, this same ideology prevails: among the aged economic independence is a fundamental value; dependency is 'demeaning' (p. 86).

In general, research has shown that in small-scale, developing societies, intergenerational family relations tend to be more mutually interdependent than in capitalist, postindustrial settings, although many important exceptions can be found (Albert and Cattell, 1994: 87–96; Sokolovsky, 2009: 110–111). A wealth of careful, detailed, cross-cultural data on generational ties has been produced by anthropologists, revealing a profound variety in

the ways intergenerational relationships are conceived, maintained, practiced, and given value.

Generation as a Principle for Structuring Society

Anthropologists have also examined the ways social and cultural groups employ some concept of generation to organize social relationships beyond the family. Many societies group people into generation-defined categories, taking some notion of genealogical succession within the family and extending it to think about broader social relations (Kertzer, 1979). Examining generation in this sense, as a principle of social organization, has allowed especially social anthropologists and those concerned with social structure to address questions about the very ordering and continuity of societies (Alber et al., 2008; Baxter and Almagor, 1978; Eisenstadt, 1956; Fortes, 1984).

In some societies, social generational ordering is highly formalized and elaborate. Rituals, variations in dress, forms of speech, permitted behaviors, specialized tasks, and places of residence may sharply distinguish persons of one generational group from another. The most highly institutionalized organizations of generations into social groupings, often referred to as *generation-set systems*, have been found among a number of East African groups (Baxter and Almagor, 1978). In such groups, the generation model is extended so widely as to provide the basis for regulating social relationships in an entire society. Every male is a member of a named generation set, and the generation set a man is in is determined by the generation set his father is in.

The crucial rule in such generation-set systems is that successive genealogical generations of fathers and sons must be socially and politically separated. Some scholars suggest that this is a way of minimizing generational conflict and competition, for instance over wives, land, and political leadership, for members of different generation sets generally cannot compete over the same resources and privileges. Generation-set systems have almost always been organized around males, and women may be tied to them peripherally as daughters, wives, and mothers. Versions of such systems have also been found in Melanesia and Polynesia, among Australian aborigines, and among some Native American groups.

Even in societies where people are not organized into formal generation sets, some notion of generation as a principle of social organization is almost universally employed (Kertzer, 1979). For instance, the social roles or identities a person assumes may depend on whether he or she represents the junior or senior generation in a family. In many societies, a person's transition to social adulthood is linked to the birth of his or her children; and in India, the transition to a 'senior' stage in life and society comes about not so much through reaching a particular chronological age but through the marriage of one's children (Lamb, 2000).

It is necessary to distinguish between generation and chronological age as principles of social organization and of cultural value. Most societies use some version of both in ordering social relations, but these categories are often confused or overlapping in social scientific analyses and among the people being studied (Kertzer, 1979). Age, however, is distinct from generation: it has to do with the chronological passage of time, and rests on the formally isolated individual as the unit of reference; whereas generation is family generated. There are many situations in which relationships by generation conflict with relationships by age. For instance, among the Tallensi, no man, even if very advanced in age, can achieve jural autonomy until his father dies (Fortes, 1984). In the United States, social criticism may ensue if a man marries a woman 'young enough to be his daughter' (the woman as wife becomes the man's generation, but has the chronological age of his children's generation).

Several anthropologists have been intrigued by the fact that what is essentially an intrafamily principle of genealogical generations has been used so widely by human groups to think about social relations outside the family. People of diverse cultures seem to find families 'good to think with.'

Generational Identity as a Facet of Social Difference

Finally, a fourth way anthropologists have approached the study of generation is as a form of identity. Since around the 1980s, anthropology has turned away from generalizations based on culture to consider the importance of difference within structures of power. The concept of generation as a form of differential identity can be used to heed the multiple, competing perspectives, experiences, and positions of inequality that make up any society or culture, as it intersects with other axes of difference such as class, race, gender, sexuality, ability, and age.

Sherry Ortner is one anthropologist to consider generation as a feature of differentiating prestige systems in her 1996 collection of essays, *Making Gender: The Politics and Erotics of Culture*. Ortner explores how generation can intersect with principles such as gender, class, and birth order in diverse ways in a range of societies, allowing her to move beyond what she describes as the 'by now rather sterile debates' over the universality of male dominance (p. 172). In a reanalysis of A.R. Radcliffe-Brown's 1920s work on the Andaman islanders, Ortner suggests a "basically gender-undifferentiated prestige hegemony" in which "age and generation were more significant axes of authority than was gender" (1996: 152–153).

Jean and John Comaroffs (1999) take a powerful look at generation as one of the dominant idioms through which youths in postcolonial South Africa frame their identities and place in the world. Widespread anxiety over the hardening materialities of life in an era of global capital translates frequently into bitter generational opposition. Many young black men blame their current incapacity to ensure a viable future for themselves on a perceived sinister, all-consuming aged elite, referred to as 'witches' or 'old ladies' (even when they are men). The Comaroffs cite one example of a group of youths pelting an old woman with sticks and stones. "'Why are you killing me, my grandchildren?' she wailed. Her assailants responded, 'Die, die you witch. We can't get work because of you!'" (p. 287). The major lines of opposition in contemporary South Africa, the Comaroffs find, are not race or class, but generation, mediated by gender. Several related essays are also published in Alber et al. (2008).

Other studies use a language of generational identity (as in post-Soviet generation, post-Civil Rights generation, one-child-policy generation) to examine historically situated processes

of identity construction that can explain significant differences in experiences, ideologies, and practices among diverse members of a society or nation.

Such work reveals the potential salience of generation as a category of social experience and analysis. A society at any given moment may be perceived, by the people within it, and/or by the anthropologists studying it, as being crosscut by generations representing powerfully divergent values, agendas, and positions of prestige.

The Importance of Generation in Future Work

Generation has been a productive lens through which to study many facets of social-cultural life in anthropology. As Alber, van der Geest, and Whyte argue, generation is a powerful analytic tool for studying society, as "it implies relations in time. Whether we think of intergenerational links within families or across historical periods, generation is about connections and contrasts – and often conflicts – in a temporal perspective" (2008: 1). The concept of generation has not emerged as a central analytic issue in the discipline, however. Many works (including several of those cited in this article) that do, in fact, examine generation in fruitful ways do not explicitly foreground their focus on generation as a central dimension of their projects. Interest in the concept of generation may, however, be increasing in the field. The category of generation can be fruitfully exploded to explore problems of current critical interest to the discipline – pertaining to the ways people envision and experience social change, how family moral systems and forms of elder care are fashioned under changing cultural and historical circumstances, and the ways diverse power structures, voices, and identities make up particular cultural worlds.

Abstract

This article offers a summary of the theory of social generations as a force in human history. It points out that rebellious youth has often challenged authority and that rebellious younger generations have become more common in recent times. It traces the emergence of a theory of generational conflict over the last century and offers some critique of this view of change in history and its consequences.

Introduction

Generations are groups of human beings born about the same time and shaped by the same social structure and the same span of history. These subdivisions of society have played a more important part in the flow of human events than is commonly realized. During the nineteenth and twentieth centuries in particular, younger generations played colorful, sometimes revolutionary roles in modern history. As awareness of the importance of generational conflict has grown, an evolving *theory of social generations* has developed to explain this phenomenon. Thinkers such as Karl Mannheim, José Ortega y Gasset, and a host of more recent scholars have analyzed the impact of social and cultural changes and of traumatic events in the shaping of human generations. Their research has also suggested that generational activism itself has increasingly become a force for social change.

Age Groups in Human Society

Age groups have been recognized in most societies and have been elaborately institutionalized in some. Like such other subsets of society as race, class, and gender, age groups have been both active forces in social conflict and creative agents of social change.

Anthropologists have detected age groups (age grades or age sets) among many preurban peoples. In these cultures, progress from one age grade to the next may be celebrated by elaborate rites of passage, and membership in a particular age group often brings both obligations and privileges. Young men will be expected to fight wars, young men and women may look forward to marriage, and both genders will have traditional work duties. Older people of both sexes may serve as decision-making elders or perform important ceremonial functions in the community.

But age groups are detectable in more complex urban societies also. Apprentices in guilds, students in schools, and conscripts in armies are subgroups in society normally defined by age. Economic and political authority is commonly exercised by middle-aged and older people. Even the elderly may be consulted for their long experience or be assigned some modest function in the community.

In most preurban cultures, younger and older people tend to accept traditional roles, rights, and social limits defined in significant part by age. In more complex societies, however, *generational conflict* between age groups is detectable – and seems to have become considerably more common in recent centuries.

There is evidence of this sort of conflict between age groups in earlier urban societies than ours. In ancient Greece, for instance, Aristotle saw differences between youth and age at the heart of the social wars that frequently rent the fabric of Greek city-states. Medieval observers were dismayed by the riotous behavior of guild apprentices or the 'town and gown' violence of university students. Many of the leaders of the European Reformation were young preachers, and historians have noted that the 'founding fathers' of the United States were actually young men.

The clearest and most impressive examples of generational conflict, however, seem to have emerged in the nineteenth and twentieth centuries.

Youth in Modern History

Western youth in 1800 had inherited an unprecedented surge of social transformation. The 1700s had seen continuing expansion of Europe's overseas empires, the beginnings of the industrial revolution, and early steps toward democracy in Europe and America. Through the nineteenth and twentieth centuries, younger generations would continue to grow up in a world of challenge and change – and would add their own vigorous demands for more of the same. Surges of reform, revolution, or even utopian subcultures thus recur throughout the history of this period.

Generational revolt was common in the nineteenth century as young people swarmed into the streets of European cities demanding political, economic, and social changes in society. *Youth movements* like the German Student Unions, the youthful French barricade fighters of the 1830s and 1848, Mazzini's Young Italy, Young Ireland, the Young Czechs, and a series of increasingly violent Russian youth movements challenged authority across the continent.

The twentieth century saw the spread of rebellious younger generations around the globe. The first half of the century saw Lenin's Communists overthrow the tsars in Russia, the Young Turks seize power in Istanbul, Gandhi build youthful opposition to British rule in India, and a series of Chinese student movements paving the way for Mao's seizure of power after World War II.

During the second half of the century, young rebels liberated colonies from European rule across Africa and parts of Asia, and young women moved to transform the workforce of the western world. In the turbulent 1960s in particular, the United States was shaken by the youthful black liberation and the anti-Vietnam War movements; young demonstrators swarmed into the streets in West Germany, France, and other European countries; a young Fidel Castro cemented his power in Cuba; and an aged Chairman Mao turned his young Red Guards loose to revive the revolutionary spirit – and saw them wreak havoc from the public squares of Chinese cities to the monasteries of far Tibet.

These two centuries of change and challenge also saw rebellious youth exercise another option besides rebellion – *withdrawal from society* in increasing numbers to carve out new lifeways for themselves.

Thus the 1800s saw young English Romantic poets praising the beauties of the natural world and the simple lives of country folk. Later in the century, young French 'bohemians' – secessionist youth identifying with wandering gypsies – appeared in the slums of Left Bank Paris, rejecting materialism to live free and poor along the wrong side of the Seine. In the first half of the twentieth century, secession from bourgeois society spread to London's Soho, New York's Greenwich Village, and similar enclaves across the western world. Later generations in many places substituted social withdrawal for political action. Arguing over the latest wave of new music, and inhaling or injecting new drugs, they turned their backs on the world their parents had built.

The sheer scale of these multifarious challenges to the existing order clearly needed an explanation. The idea that seems to answer this need best is the notion of the social generation.

Emergence of the Generational Idea

Theoretical understanding of the generational dimension of human society had in fact evolved as conflict between generations grew more visible.

Earlier cultures had developed at least some awareness of this factor in society. In ancient times, Old Testament genealogies and Homeric poetry reveal clear concern with the succession of human generations. The traditional father of history, Herodotus, posited 33-year generations in his *History of the Persian War*. The Arab world historian Ibn Khaldun proposed a basic theory of generations in his *Muqaddimah: An Introduction to History*.

Only in the nineteenth century, however, did modern social thinkers of the caliber of Auguste Comte, John Stuart Mill, and Wilhelm Dilthey begin to develop a coherent and convincing theory of social generations. Julián Marías, a leading historian of the generational idea, emphasized the major contributions of these men. Comte, Marías pointed out, had clearly recognized the succession of generations as an important causal factor in social change. Mill was well aware that the generational concept must be expanded beyond the traditional familial or genealogical framework to encompass society as a whole. And Dilthey had attempted to analyze the basic structure and broader significance of the social generation in human society.

The first half of the twentieth century – particularly the period between the two world wars – saw classic formulations of the theory of social generations by the Spanish philosopher Jose Ortega y Gasset (1923, 1933) and the German sociologist Karl Mannheim (1928).

Ortega's account of the phenomenon focused on the internal development of the typical generation. He divided the human life span into four 15-year stages – childhood, youth, initiation to positions of power, and domination of society. This stages-of-life perspective, rooted in the psychological and social stages of human development, has influenced many generationists since.

Karl Mannheim's analysis emphasized the roots of generational differences in the changing social and cultural circumstances that shape each new generation. Emerging generations are thus influenced by their social *location* in a particular social class, by the rural or urban environment in which they grow up, and by new trends in the society in which they live. In changing times, generations may develop different points of view and patterns of behavior from those prevalent among their elders. Mannheim also analyzed the structure of the social generation. He suggested that a given birth cohort might be subdivided into a number of distinct *generation units*, social subgroups who 'work up' the common generational experience in very different, sometimes ideologically conflicting ways.

In the wake of the global pandemic of youth revolts in the 1960s, finally, scholars and other concerned commentators probed the patterns of generational development and conflict as never before. Such students of the generational phenomenon as T. Allen Lambert (1972), A. B. Spitzer (1973), Marvin Rintala (1979), Richard Braungart (1986), and Shmuel N. Eisenstadt (2005) developed a convincing model of the social generation as a force as powerful as the social class in human history. Other generationists, including D. Sinha (1972), Anthony Esler (1972), Wilhelm Pinder (1979), Mark Roseman (1995), and Joe Austin and Michael N. Willard (1998), focused on the role of generational conflict in the history of particular countries and cultures over the nineteenth and twentieth centuries.

These scholars probed the sociopsychological roots of generational consciousness in immense detail. They documented the persistence of a sense of generational identity even after a strong involvement with one's youthful peer group has faded. And they collected masses of contemporary evidence of the existence of generational conflict and of its influence on social change.

The Theory of Social Generations

In the twenty-first century, generational analysis is used by historians, political scientists, sociologists, anthropologists, and critics of literature and the arts. The concept has also proved useful to journalists, politicians, marketing experts, and many others concerned with understanding or influencing society. These diverse commentators explore *age groups* just as they do groups defined by social class, gender, or ethnicity. The brief exposition of a developed, essentially Mannheimian view of the social generation that follows will also draw on this broad range of insights.

A *social generation*, then, is a *birth cohort*, a group of individuals born in the same place and period and in similar circumstances. Shaped by common cultural, social, economic, and other influences, members of the same generation develop similar perspectives during their early years. Children of wealth, private schooling, and unlimited opportunity will grow into a very different kind of adult from the offspring of poverty, little opportunity, and no preparation to take advantage of any that should appear.

Within this framework, common family structures, child-rearing methods, and educational practices begin the process of *socialization*. A patriarchal philosophy of "spare the rod and spoil the child" and an education built around rote memorization, for instance, may tend to produce one sort of *generational conscious*. Permissive child-rearing methods and educational patterns dedicated to developing the individual propensities of students may begin the shaping of a very different sort of social generation.

As the cohort matures through adolescence and youth, the larger social framework within which this process takes place also exerts powerful shaping influences. Hierarchical or more egalitarian societies, traditionalist or rapidly evolving cultures, authoritarian or democratic political systems – all of these have an impact on young people as they emerge into the world beyond the family.

Within this larger milieu, the specific *social location* within which a particular subgroup of a given generation matures will also have its influence. Young people raised in working-class communities may grow up with a very different view of the world from that of youth raised in middle-class suburbs or among the even more affluent. At every level, the pages young people read, the songs they hear and sing – and, in more recent times, the films they watch and the electronic world they explore – shape the perspectives, beliefs, and values of a social generation.

To these influences of home, school, and society, however, historical study of the generational phenomenon would add a special emphasis on *traumatic historical events* or *disturbing social trends* in the shaping of a rebellious younger generation.

Accounts of specific generations have tended to stress this impact of disturbing events upon the young. Unsuccessful wars or brutal economic downturns may turn the younger generation against a society that seems to have failed. Such historic cataclysms may deeply undermine the view of the world – and their place in it – that these young people had been taught in childhood. The result may be a disillusioned and rebellious generation that turns against the world their elders made.

The mores of a younger generation may thus be drastically reshaped as they shrug off the prescriptions of their 'deauthoritized' elders (Feuer, 1969). Especially where antiestablishment ideas are already in the air, such historical traumas may turn advocates of change into leaders of generational rebellion.

It is sometimes difficult to trace the long-term impact of generational revolts. Such youthful upheavals as the wave of political revolutions against European monarchies that exploded in 1848 – or the surge of demonstrations by young black Americans against a segregated society in the 1960s – did not transform either European politics or American society overnight.

In time, however, the activism of rebellious youth often does leave its mark on history. The European 'forty-eighters' were vigorously suppressed by royal troops in the Revolutions of 1848. But in the decades that followed, the legislatures of at least some European nations grew more democratic and claimed increasing power. And in the wake of World War I, the hereditary monarchies and aristocracies faded away as a primary force in European politics.

In the 1960s in the United States, the young black demonstrators who followed Martin Luther King, Jr., into the streets got some liberalizing laws passed but did not abolish the United States' inner-city ghettos, and King himself fell to an assassin's bullet. But the demonstrators of the 1960s had opened doors for some black Americans, and white attitudes did begin to change. Fifty years on, King's statue stood on the Mall in Washington, and a black president sat in the White House.

Problems and Potential of Generational Analysis

The range of specific uses to which generational analysis has been put is broad and continues to expand.

There is a large literature focusing on younger generations mobilized in politically motivated student or youth movements. The generational approach has also been utilized by historians and critics to characterize the periods of transformation in literature and the arts. Other scholars have probed social innovations and social trends pioneered by younger generations. Studies of the liberation of women over the last century and of the more recent electronic transformation of work and play have found generational analysis useful. And attempts to estimate the damage done to a society by such group experiences as a war or a major depression often detect clear generational divides.

Like any attempt to explain the group lives of human beings, however, the theory of social generations has raised its share of challenging questions.

A generation is by definition a group of people born during the same span of time – but how long should that span be? Thirty-three years as Herodotus declared, 15 years with Ortega y Gasset, or as little as 3 years, as some modern demographic studies might suggest? In the end, the length of a generation that makes a difference in history seems to depend on the pace of social change in the period in question. The more rapidly the shaping social matrix changes, the more quickly enough changes accumulate to produce a new generational point of view.

Another important question for the skeptic, perhaps, would be "Are social generations in fact as *real* a force in society as race, class, or gender?" Some observers have noted that even when the streets surge with young demonstrators, most young people seem to be at home, sharing their parents' lives and views. In history, however, numerical majorities are not necessary to produce significant consequences. When socialization fails with a critical mass of the young, the resulting surge of generational activism can produce revolutionary changes in the world they live in.

But, yet another body of generational research suggests, are there not also identifiable generations whose shared qualities

of mind and feeling do not in fact exercise powerful influence on the course of history? Are there cohorts identifiable through lifestyles and mind-sets, customs and costumes, who often seem to be not shapers of the course of events in their time but victims of it? Highly developed generational subcultures may in fact emerge with neither a transforming impulse nor a belief that significant change is possible. But romantics and bohemians, and the 'Lost' and 'Beat' generations, may still leave artistic or cultural legacies that are no small gift to their successors.

And a final query, rooted in the present time – early in the twenty-first century – might be "How active a force for change *are* younger generations in our time?"

A decade into the 2000s – and half a century after the 1960s – a new surge of youthful protest seems in fact to be building around the world. The 'Arab Spring' of 2011 toppled old dictatorships in Egypt, Libya, and other Muslim lands in North Africa and the Middle East. Desperate economic times have recently filled European streets from Greece to Portugal with demonstrators and burning buildings. In China, an astonishing 200,000 local protests, often over land-devouring urbanization, have challenged the authoritarian government in Beijing over the last 5 years. And in the United States, jobless young people moved in to 'Occupy Wall Street' at the end of 2011 – and youthful dissenters were soon mobilizing to 'occupy' key protest sites in their own countries around the globe.

It might not be 'the 1960s' yet, but it does suggest a future for generational activism as a force in human history.

Abstract

Political generations are politically distinctive age groups delimited by their years of birth or by some major political event. Societies are transformed through the processes of birth, aging, and death, but this transformation may or may not lead to political change. This article examines the way replacement has contributed to the rise of the Democratic Party in the United States during the 1930s and 1940s, increased tolerance in the last two decades, and the decline of electoral participation since 1960. In Britain, replacement led to the dominance of the Labour Party after World War II, but it later led to the decline in party loyalties. In Israel, it led to the decline of Labour. Through his study of value change, Inglehart has made the most important contribution to the study of generational change, and the data he collected between 1970 and 2006 strongly suggest that replacement was a major factor contributing to the rise of Postmaterialism.

'Political generations' are politically distinctive age groups delimited by their years of birth or some major political event, such as their years of entry into the electorate. Rintala (1979: p. 8) defines a political generation as "a group of human beings who have undergone the same basic historical experiences during their formative years." According to Braungart and Braungart (1989: p. 283) "a political generation is an age group in history that mobilizes to work for political change," although in principle an age group could work to maintain the status quo.

Generation and Cohort

Birth, aging, and death gradually transform societies. Unless there is a world war (Snyder, 2010; Weinberg, 2005), genocide (Rummel, 1994), pestilence (Herlihy and Cohn, 1997), or massive human emigration or immigration, these natural processes are the main forces transforming societies. Birth, aging, and death may or may not transform societies. The young may resemble the old in their political behavior and, even when young adults do differ from their elders, they may come to resemble them when they themselves age.

But although each generation perpetuates society, it may also change it. If the young could be isolated from their elders, it would be easier to create a new social order, and Plato argued that philosophers could establish a new society more quickly if they expelled all citizens above the age of 10 from the Republic (*Republic* 54a). The *Book of Numbers* relates that the generation freed from Egypt, which again and again showed its faithlessness, was condemned to have their corpses consumed in the wilderness until a new generation, reared in freedom, was ready to conquer Canaan (14:29; 14:32). Both the *Hebrew Bible* and the *New Testament* reveal great interest in generations.

Generations can apply to personal records or to the ancestors of a group. As Wilson (1992) writes, genealogies are rare in Ancient Near Eastern literature. They sometimes appear in lists of Mesopotamian and in 2d-milllennium texts dealing with the political history of the Amorites. However, Wilson notes that the *Hebrew Bible* contains 25 genealogies of various complexity. The *New Testament* provides two genealogies of Jesus (*Matthew* 1:1–17 and *Luke* 3:23–38).

Other political systems have their founding legends, and in his epic Virgil explains how Aeneus, the son of Anchises and Venus, becomes the head of the surviving Trojans and leads them to found Rome. Some legends trace the British royal family back to the Trojans. Generational conflict is a basic theme of several of Shakespeare's tragedies, such as *Hamlet*, *King Lear*, *Macbeth*, and *Coriolanus*, and generational conflict plays a major role for twentieth-century writers, most notably in Faulkner's novels, especially his *Absalom, Absalom* (1936).

Although the concept of generations has biblical, Greek, and Roman roots, the social scientific study of political generations began with Mannheim's essay, 'The Problem of Generations' (1952 [1928]). According to Mannheim (1952) the concept of generations is both biological and sociological. Generations are produced through both "the biological rhythm of human existence," but "individuals who belong to the same generation, who share the same year of birth, are endowed, to that extent, with a common location in the historical dimension of the social process" (p. 209).

Mannheim (1952) maintains that historical experiences are most likely to be shared by persons in their late adolescence and early adulthood, postulating that 'personal experience with life' usually begins at about age 17. Whether young people are actually influenced by historical events depends upon social and historical conditions. Furthermore, young adults living in some historical conditions may experience quite different events, even within the same society. Nor do all historical conditions produce conditions that influence young adults in distinctive ways. Mannheim emphasizes that distinctive generations are more likely to form in periods of rapid social change. But his basic point is that there is no guarantee that socially or politically distinctive generations will emerge. "Whether a new *generation style* emerges rhythmically at all, depends entirely on the trigger action of the social and cultural process" (p. 310).

Distinctive generations emerge in times of rapid social change. Many contemporaries viewed the French Revolution as a time of unprecedented change. As Wordsworth (*The Prelude*

[1805, Book Tenth, lines 108–109]) wrote, "Bliss was it in that dawn to be alive, But to be young was very heaven!" Although Condorcet lacked both the ability to write flowery poetry or clear prose, he saw the French Revolution as an event that might bring female equality and the emancipation of slaves (1802). The Americans who served in World War II, were often in their thirties, but Brokaw (1998) famously labels them *The Greatest Generation*.

Following Mannheim's (1952 [1928]) cautions, it is unwise to label a group of people a political generation unless one can establish that they are actually distinctive in their attitudes and behaviors. Therefore, social scientists need a term describing people born during the same years, but making no other assumptions about their distinctiveness. The term 'cohort' is used to describe a distinctive birth group. The term derives from a military unit in a Roman legion, but the term now has a much broader meaning. Scholars usually define a cohort by its years of birth, often grouping respondents in 10-year-old categories in order to save one column on the IBM punch cards that once were used to be used to store data. Scholars who want to work with these early data needed to use these arbitrary age categories. With computerized storing, survey data are usually coded according to year of birth giving analysts greater flexibility. For example, in a major cohort analysis, Converse (1976b) divides his data into 3-year categories, and throughout their study of the electorate, Miller and Shanks (1996) generally divide their cohort results into 4-year categories. In the 2012 American National Election Study (ANES) survey, the policy of providing actual year of birth was abandoned and 5-year categories were used. In 2012 face-to-face interviews were supplemented by an Internet survey. Researchers feared that if this "Big *N*" approach included the respondents' year of birth anonymity might be compromised. But by not measuring the respondents' years of birth ANES is jeopardizing over-time comparability.

The Impact of Generational Replacement

The population is gradually transformed through generational replacement. (Some scholars use the term 'cohort succession.') Replacement can play a major role in transforming the political attitudes and behavior among mass publics. For example, during the 1930s and 1940s replacement helped make the Democrats the majority party in the United States (Campbell et al., 1960), and during the postwar years replacement contributed to eroding party loyalties (see Abramson 1976, 1979, 1983, 1989b; but see Converse, 1976b). Replacement benefited the British Labour Party during the 1960s (Butler and Stokes, 1969, 1974[1969]), but it contributed to the erosion of British party loyalties between 1964 and 1987 (Abramson, 1992). Between 1969 and 1988, replacement contributed to the decline of the Labour Party in Israel (Abramson, 1989a). Replacement may also help transform political values. For example, replacement helped to increase tolerance in the United States between the mid-1950s and the mid-1970s (Abramson, 1983). Women who came of age after the enfranchisement of women by the Nineteenth Amendment played a major role in increasing women's turnout (Firebaugh and Chen, 1995).

Miller (1992) argues that the decline of turnout in American elections largely results from the entry of a post-New Deal generation into the electorate (see also Miller and Shanks, 1996). That change, Miller contends, resulted not only from their youth, but also from generational differences that contributed to low levels of participation. During the 1960s and early 1970, a series of events – the Vietnam War, the Watergate scandal, and the perception that Gerald R. Ford and Jimmy Carter were failed presidents – created a generation that withdrew from political activity. In his *Bowling Alone*, Putnam (2000) explores the impact of aging and generational succession, and argues that political disengagement largely resulted from the baby-boom generation coming of age. He writes (p. 265), "The declines in church attendance, voting, political interest, campaign activities, associational memberships, and social trust are attributable almost entirely to generational succession." Along with Campbell (Putnam and Campbell, 2010), he further documents that replacement contributed to the decline of religiosity and for growing tolerance toward homosexuality (Putnam and Campbell, 2010). For more specific information on generational change in Canada, Québec, Great Britain, Italy, and France, see the volume edited by Crête and Favre (1989).

Whenever there is a dramatic shift in public opinion, along with substantial differences between age groups, the shift probably results from a combination of changes among the existing public and generational replacement. The growing support for same-sex marriage in the United States provides an example, although further research will be necessary to understand the dynamics at work. For example, three public opinion polls (accessed through http://pollingreport.com) show increased support for same-sex marriage. For example, a Gallup poll of about 1500 adults showed that in May 2006, 42% said that same-sex couples should have the right to have legally valid marriages; by May 2013, 53% did. A CBS/*New York Times* poll of about 2000 respondents found that in March 2004, only 24% said Americans should be allowed to marry legally; in February 2012, 40% did. And in an ABC/*Washington Post* poll of about 1000 respondents conducted in November 2003, only 37% said it should be legal for gay and lesbian couples to legally marry; by March 2013, that figure had risen to 58%. Young Americans are consistently more likely to support legal same-sex marriages than their elders. In July 2003, a large CBS/*New York Times* poll of 3000 Americans showed that among those between 18 and 29 years old, 61% said that homosexual couples had the right to marry, whereas among those 65 and older, only 18% did. And in a March 2013 CBS poll of 1000 respondents, 73% of Americans between 18 and 29 thought it should be legal for same-sex couples to marry; among those 65 and older, some 35% did.

Ronald Inglehart and the Study of Generational Change

By studying values for over four decades, Inglehart has made a major contribution to the study of political generations. In 1971 he reported that younger Europeans had substantially different values than did their elders. Whereas older Europeans

tended to value material security and domestic order, younger Europeans were more likely to value political liberties. Inglehart (1971) initially labeled these priorities as 'acquisitive' and 'post-bourgeois,' he subsequently (1977) used the terms 'Materialist' and 'Postmaterialist.' Although Inglehart initially had surveyed in Belgium, Britain, France, West Germany, Italy, and the Netherlands, he speculated that age-group differences probably resulted from the formative socialization of younger and older Europeans, although he acknowledged that they might result partly from higher levels of education among the young. Even if economic conditions did not remain as rosy after 1971, it seemed highly unlikely that Europeans born after World War II would suffer from the extreme deprivation of Europeans who grew up before or during World War II or from the deprivations of the post-War years. And there were many reasons to expect them to have higher levels of education than their elders.

Many scholars viewed Inglehart's prediction as a major insight. Almond (1990) argued that 'Inglehart's work is one of the few examples of successful prediction in political science.' The authors of the five-volume *Beliefs in Government* series find an overwhelming of a shift toward a redefinition of the Left–Right continuum. Scarbrough, who analyzes Materialist/Postmaterialist orientations, concludes (1995: p. 156), "indisputably, across much of Western Europe, value orientations are shifting." General editors, Kasse and Newton (1995: p. 61), sum up the findings: "We find substantial support for the model which traces social change to value changes, and value changes into political attitudes and behaviour, especially through the process of generational replacement." And in his discussion of value change Dalton (2014: 89) concludes, "The most influential research is Ronald Inglehart's theory of value change in advanced industrial societies."

Beginning in the mid-1980s, Inglehart and I began collaborative work to demonstrate that the trend toward Postmaterialism was largely the result of generational replacement. We employed an algebraic standard procedure that I used to study attitude change in the United States (Abramson, 1983). To demonstrate how this procedure works, I examined the percentage of high school graduates among the white electorate between 1956 and 1980, assuming that no new cohorts were allowed to vote. But this procedure would not account for the tendency of older Americans to die at higher rates than the younger. Thus, I algebraically 'immortalized' the older cohorts, assuming that their distribution remained unchanged. This procedure seemed justified since people do not become less educated with age, although, as Swift's (2002[1726]) *Struldbruggs* discovered, immortality can carry a heavy price. But when other political attitudes or behaviors are imputed to a cohort that has dropped out of the sampling frame through death or institutionalization, we do not know what their attitudes would have been if they had survived. For example, my first cohort analysis of the decline of party loyalties among American whites began with seven 8-year cohorts, the youngest of which was born between 1924 and 1931. In 1952, when party identification was first measured, that birth cohort was between the ages of 21 and 28. By the 2012 election, this cohort was between the ages of 81 and 88. Moreover, given changes in ANES sampling procedures (mentioned earlier) this cohort cannot be identified. But even if we could, the U.S. Bureau of the Census data show that only 5% of the noninstitutionalized white population in 2012 was old enough to have voted in the first Eisenhower–Stevenson contest. Whites who were 75 years old and older made up 6% of the sample, but a small percentage of them would have been too young to have voted in 1952.

As Inglehart first began to survey the European public in 1970, and since he sampled Europeans as young as 16, problems of cohort attrition are not as great as those confronting social scientists who rely upon the ANES surveys. However, the method I developed to analyze the effects of generational replacement had begun to affect the ongoing data that Inglehart has collected as President of the World Values Survey.

Before discussing these problems, however, it is fair to note that some scholars disagree with Inglehart's basic thesis and question his basic measure, which is based upon respondents choosing their top two national goals out of four choices. (A less frequently used measure asks them to choose their top six choices out of 12 goals.) Inglehart's data are readily available. We describe them in our book and the SPSS procedures for constructing them are available in Inglehart (1997: p. 389).

Inglehart has always archived his data and made them readily available to the social science community. In doing so, he conforms to the fundamental tenets of scientific research, but he also exposes himself to criticism, although in some cases critics have generated their own data. In a recent paper (Abramson, 2011), I reviewed 54 critiques of Inglehart's work. Many of these critiques were helpful, although many were based upon a misunderstanding of Inglehart's basic thesis. In this essay, I will focus only on the way these arguments shed light on the study of political generations.

By the early 1980s it was clear that Postmaterialism was not following a simple trend upward (Inglehart, 1981), but that the views of the European public also responded to short-term forces, or in the language of cohort analyses, the public responded to period effects.

Our book (Abramson and Inglehart, 1995) presents our most extensive treatment. We examine evidence from 40 societies, seven wealthy societies in the European Community (now the European Union), four less wealthy societies in the European Community, five West European societies not in the European Community, two North American countries, four Latin American countries, five East European societies, six former Soviet societies, one Middle Eastern society (Turkey), two Asian countries (China and India), two East Asian countries (Japan and South Korea), and two African countries (Nigeria and South Africa). Although we present the relationship between Postmaterialism and age and the mean rate of economic growth for the previous three decades, our cohort analyses focus mainly upon eight European democracies: Belgium, Britain, Denmark, France, Ireland, Italy, the Netherlands, and West Germany. At times we use a weighted national sample of Belgium, Britain, France, Italy, the Netherlands, and Germany (the only countries in the series sampled in 1970).

Our main conclusion is based upon our algebraic standardization procedures. The score on the Postmaterialism index (PDI) is computed by subtracting the percentage of Postmaterialists

from the percentage of Materialists. The measure ranges from a low of −100 to a high of 100, with 0 indicating an equal number of Materialists and Postmaterialists.

We present the PDI scores among cohorts for all eight countries and then discuss the possible effects of replacement, drawing upon Abramson (1983). We then estimate the effects of replacement for all eight societies as well as for a combined weighted sample of the six countries sampled from 1970 to 1992. We then estimate the effect of replacement for all eight societies as well as for the combined European sample. In 1970, only 11% of the West European publics were Postmaterialists, whereas 40% were Materialists, a PDI of −29. In 1992, 16% were Postmaterialists and only 26% are Materialists, a PDI of −10. During these two decades there had been a 19-point shift toward Postmaterialism. In the 1992 samples, 42% of the respondents were too young to have been sampled in 1970 and some had not yet been born.

According to our estimates, if there had been no generational replacement Postmaterialism would have increased only about two points between 1970 and 1992. In other words, only about one-tenth of the shift toward Postmaterialism would have occurred without replacement. These results also correspond to multivariate analyses (Abramson et al., 1997; Abramson and Inglehart, 1996; Inglehart and Abramson, 1994) showing that when inflation and unemployment are controlled, PDI scores increase at about one point per year, very close to the rate Inglehart's model predicts.

Since our book was published there have been several critiques, but we have already responded to most of them. The two most important were published in the *American Political Science Review* (Clarke et al., 1999; Davis and Davenport, 1999) and we have replied to both of them (Inglehart and Abramson, 1999).

More Recent Changes in Postmaterialism

Inglehart's recent study with Welzel (2005) briefly discussed the impact of generational replacement on the trend toward Postmaterialism, but they do not present the algebraic standardization procedures employed by Abramson and Inglehart. Perhaps this is just as well because ongoing generational replacement has further reduced the cohorts that can be tracked over time. However, Inglehart supplied me with a figure based upon a combined weighted sample of the six European countries that can be tracked between 1970 and 2006. This figure is available in Abramson (2011). It shows the results for 10 cohorts. The dark line shows the overall level of Postmaterialism for the entire sample.

The figure reveals five basic findings. First, it demonstrates that replacement occurs. Three cohorts in the first samples, conducted in 1970, cannot be tracked over the 36-year period. Granted, there are some centenarians in these societies, but not enough to be sampled. By 2006, even the cohort born between 1916 and 1925 was between the ages of 81 and 90. Many were institutionalized and because of differential death rates the cohort would be very heavily female. During these three and a half decades, three full cohorts born between 1986 and 1991 entered the sample. In fact, 45% of these younger Europeans had not been born when these surveys began. Although Firebaugh (1989) makes excellent suggestions for dealing with the problem of 'non-surviving' cohorts, all are based upon problematic inferences.

Among the respondents sampled in 2006, only 40% were old enough to have been sampled in 1970. Among the cohorts that did survive, the cohort composition was substantially different than it was in 1970. As the figure shows, the largest cohort differences are between Europeans born between 1936 and 1945 and those born between 1946 and 1955; that is, between cohorts that suffered through World War II and the postwar deprivation and those who came of age when Western Europe began to prosper. In 1970 among cohorts born before 1956 (and thus old enough to have been sampled in 1970), 86% were born before 1946. But by 2006, only 57% were.

Second, the figure demonstrates consistent cohort differences across time among the cohorts born before 1956. Among these cohorts the younger cohorts have higher levels of Postmaterialism than their elders and there are few breaks in monotonicity. The 1956–65 cohort is significantly more Postmaterialist than the 1956–65 cohort, a finding consistent with Inglehart's thesis since the 1956–65 cohort grew up under far more secure conditions.

Third, there are few differences among the four youngest cohorts. Despite moderate economic growth, rising levels of economic inequality have led to little or no increases in real income for most Europeans. Economic security has been reduced by cutbacks in the welfare state and high levels of unemployment, especially among the young.

Fourth, the figure demonstrates no support for a life-cycle explanation for age-group differences. If a life-cycle interpretation for the Postmaterialism of the younger cohorts were valid, we would expect, other things being equal, these cohorts to become more Materialist as they age. They do not. Moreover, the older cohorts gravitate toward Postmaterialism. One can always assume that these cohorts would have become more Materialist with age, but that period effects prevented such a move. But I know of no plausible explanation supporting such an interpretation. Of course, we know that the trend toward Postmaterialism does not result from replacement alone, for there are also short-term fluctuations caused by changing inflation rates (Abramson and Inglehart, 1994; 1995: pp. 25–39).

Finally, the figure strongly suggests that the overall shift toward Postmaterialism is at least partly driven by replacement. Because fully 60% of the 1970 sample can no longer be sampled in 2006, using the algebraic standardization procedure Inglehart and I applied from 1970 through 1992 (Abramson and Inglehart, 1995) is problematic. All the same, even an informal examination of the figure demonstrates the importance of replacement. Recall that in 1970 the PDI for this six-nation sample was −29. In 2006, 19% were Materialists, while 21% were Postmaterialists, a PDI of 2. Overall, there was a 31-point shift toward Postmaterialism. But while this shift is reflected in the solid trend line representing the overall level of Postmaterialism, none of the cohort gains is close to this magnitude. Comparing the overall trend line with the trend line for the cohorts makes this clear. The overall rise in the PDI scores occurs at least in part because over this third of a century the older, more Materialist

cohorts were gradually being replaced by younger, more Postmaterialist cohorts.

Some of Inglehart's critics would argue that his measure is meaningless (for a summary, see Abramson, 2011). If so, so is the trend. But there is overwhelming evidence that Postmaterialists differ in important ways from the Materialists they are replacing. Dalton (2014) provides an excellent summary. In the workplace, Postmaterialists are more likely to want a flexible work environment. In social relations, the rise of Postmaterialism leads to declining deference toward authority. Postmaterialism has led to changing moral standards. The rise in Posmaterialism has led to a shift of the issue agenda, with Postmaterialists being more concerned about the environment, gender equality, and multiculturalism. Finally, Postmaterialism affects political participation because it leads to participation in decisions affecting one's life. Although the growth of Postmaterialism may not lead to genuine revolutions, it may have the more benign effect of moderately transforming Western societies.

Abstract

Generations represent an important element in the social structure, alongside social class, race, and gender, but they have often been neglected in contemporary sociology. However, from a historical and comparative perspective, generations have played an important role in social change in terms of youth revolts against the established order. In the twentieth century, generational conflict over values and resources was important in the aftermath of the First World War, the Great Depression, and the youth movements of the 1960s. Indeed, the Baby Boomer Generation is often regarded as a crucial aspect of the transition of the West to a consumer society.

Generations, Cohorts, and Consciousness

Generations, alongside social class, ethnicity, and gender, are basic building blocks of the social structure, but they have often been neglected in mainstream sociology. The definition of generations and recognition of their sociological importance are associated with the work of Karl Mannheim (1952) and Maurice Halbwachs (1992) who established the basic components of the sociological perspective on generational change in terms of the importance of a shared culture and rituals in constituting the collective memory of a generation. Halbwach's perspective on collective memory was important in following the tradition of Emile Durkheim's notion of collective representations. Mannheim's approach was shaped by his own experiences of the political instability of Europe, the rise of fascism, and the alienation of youth. The sociology of generations is consequently a well-established tradition in modern sociology. However, there are a number of analytical problems with the concept that should be distinguished from the related ideas of cohort and age grades. Cohorts are simply aggregates of individuals born at the same time and passing through time, whereas generations, in order to have an impact on social change, typically possess a generational consciousness. In this respect, there is a parallel between class analysis with its emphasis on class consciousness and class conflict and generational consciousness and generational conflict (White, 2013). Generations and generational differences can play an important role in both political and social movements. The nationalist/revolutionary movement of Central and Eastern Europe in the late nineteenth to early twentieth century and the youth and student rebellion of the 1960s are prominent examples of the influence of generational consciousness, couched in the symbolism of youth. In contemporary sociology, interest has focused on consumption patterns and generational change, and on youth cultures and generational differences, for example, around 'The Sixties' and the 'Baby Boomers.' Finally, there is the notion that, while in the past generations were national phenomena of relevance to nation-states, with globalization one can consider the possibility of global generations with an emerging cosmopolitan awareness (Edmunds and Turner, 2005).

Generations constitute – just as the closely related categories of age, youth, adulthood, and old age – seemingly universal categories in all human societies signifying the different stages of human life; the same is true of tensions between generations, as well as of concepts of the age group or set – in particular the youth group – as a special social category with its own distinct self-consciousness. But it is only in very specific civilizational and historical circumstances that these features come together. It is only in special circumstances that historical change becomes articulated in terms of generational consciousness in general, and that of youth in particular.

It was Karl Mannheim – as well as J. Marias and J. Ortega y Gasset – who emphasized the apparent universality of generational consciousness or at least posed it as a major problem of research, but this tendency, at least as reported by them, was indeed very closely connected to rather specific civilizational traditions – the European ones – and to specific historical circumstances in the development of this civilization. Accordingly, a central problem in the analysis of generations is under what conditions does historical change become articulated in terms of generational consciousness in general and that of youth in particular?

The consciousness of a generation is often defined by traumatic historical events that shape not only the consciousness and identity of a generation but also its life chances and resources. We can examine several well-known examples. The First World War had an immediate and devastating impact on the mental and physical health of the young men who were involved, but there were also long-term implications for their personal development and opportunities. The trenches were also seen as defining the manhood of an entire generation of young men – the so-called Generation of 1914 – and the following generation that came to manhood in the interwar years had a sense of lack (Wohl, 1979). However, perhaps the important illustration of this argument is the effect of the Great Depression on the generation that came to maturity in the economic crisis that severely limited their opportunities for education and employment over the course of their mature years. This generation was famously described in Glen Elder's

Children of the Depression (1974). In more recent history, Mao Tse Tung's cultural revolution that involved sending thousands of young people to work in the countryside created a generation that was defined by its lost opportunities. The Baby Boomer generation by contrast was a postwar generation that benefitted considerably by the expanding economies of the postwar period with the welfare state, Keynesian economic politics, and by the consumer boom of the 1970s (Binstock, 2010). Their political consciousness was also defined by wars primarily by opposition to the Vietnam War and by other historical events – the Kennedy Assassination, the killing of Martin Luther King, the Beatles, and the landing of men on the moon (Eyerman and Turner, 1998).

We can conclude that where exactly people are born and the historical events that shape their life chances have importance for defining the resources, culture, and consciousness of different generations passing through time. Sociologists have proposed that the distinction between a class for itself and a class in itself could by analogy be applied to generations (Edmunds and Turner, 2002). Thus, active generations are large cohorts that have strategic advantages that are made possible by the specific circumstances that open up opportunities to exercise political and cultural influence. Passive generations occur in historical circumstances that offer limited opportunities and life chances. This distinction is implicit in the contrast that is often made between the Baby Boomers and Generation X, where the latter is seen to be apolitical and passive.

Youth as a Liminal, Transitory Phase; Kernels of Generational Consciousness

The problems of age definition and the linkage of personal time and transition with cosmic time become very often accentuated in that age span usually designated as youth – which constitute in most societies the most liminal of age definitions – the transition from childhood to full adult status, to full membership in the society. In this period, the individual is no longer a child (especially from the physical and sexual point of view) and is ready to undertake many attributes of an adult and to fulfill adult roles. But adolescent individual is not yet fully acknowledged as an adult, a full member of the society. Rather, he or she is being, as it were, 'prepared,' or is preparing for such adulthood.

This image of youth – the cultural definition of youth – contains all the crucial elements of any definition of age, usually in a specially articulated way, and often in confrontation with other age categories. Moreover, in this phase the problem of the linkage of the personal temporal transition with cosmic or societal time becomes extremely acute.

The fullest, the most articulate, and definitive expression of these archetypal elements of youth and of their liminal potentials is best exemplified in the ritual dramatization of the transition from adolescence to adulthood, such as the various *rites de passage* and ceremonies of initiation in primitive tribes and in ancient civilizations. In more diluted form, these elements may be found in the various spontaneous initiation ceremonies of the fraternities and youth groups in modern societies (Bettelheim, 1954; Erikson, 1963, pp. 54–93). Hence, the youth period and its symbolism, and the liminal situations in which it becomes expressed, may become the focus both of continuity of the social order as well as of protest against it, and of its change.

The very emphasis on the transitory nature of this stage and on its essentially preparatory character, however, often create a somewhat paradoxical situation – namely, an image of youth as the purest manifestation and repository of ultimate cultural and societal values of all the major human virtues and primordial qualities. Such an image may be reinforced by the identification of physical vigor in youth with a more general flowering of the cosmos or the society. It is this situation that contains the kernel of the development of strong generational consciousness especially around the image of youth, with strong potentialities of protest.

The social organization of any age and especially of the period of youth is constructed in all societies according to two major criteria. One is the extent to which age in general and youth in particular form criteria for the allocation of roles in a society, whether in politics or in economic or cultural activity – aside from the family, of course, where they always serve as defining principles. The second is the extent to which within society there develop specific age groups, specific corporate organizations, composed of members of the same 'age,' such as youth movements or old men's clubs.

The Social and Cultural Contexts of Different Patterns of Age and Generational Symbolism and Organization

The importance of age as a criterion for allocating roles in a society is closely related to several major aspects of social organization and cultural orientation. The first aspect is the relative complexity of the division of labor. In general, the less complex an organization, the more influential age will be as a criterion for allocating roles. Therefore, in tribal or preliterary traditional societies, age and seniority constitute basic criteria for allocating social, economic, and political roles.

The second aspect is that the major value orientations and symbols of a society, especially the extent to which they emphasize certain general qualities, or types of activity (such as physical vigor, the maintenance of cultural tradition, and the achievement and maintenance of supernatural prowess) become expressed and symbolized in specific age spans. For instance, in those societies in which military values and orientations prevail, young adulthood is emphasized as a very important – sometimes even as the most important – age, while those communities in which sedentary activities prevail emphasize older age. Similarly, within some traditional societies, where older people may serve as important a receptacle of collective memory, old age may be emphasized if it is seen as the most appropriate one for expressing major cultural values and symbols – for instance, the very upholding, symbolization, and perpetuation of a given cultural tradition.

The social and cultural conditions that determine the extent to which specific age groups and youth groups develop differ from the conditions that determine the extent to which age serves as a criterion for the allocation of roles. At the same time, the two kinds of conditions may be, in some situations or

societies, closely related. Age groups in general and youth groups in particular tend to arise in those societies in which the family or kinship unit cannot ensure (or occasionally even impede) the attainment of full social and political status on the part of its members. These conditions appear especially, although not uniquely, in societies in which family or kinship groups do not constitute the basic units of the social division of labor. Membership in the total society (citizenship) is not defined in terms of belonging to any such family, kinship group, or estate, nor is it mediated by such a group.

The emergence of distinct age and generational organization and consciousness, as Meyer Fortes has shown in one of his last papers, lies in the political realm, in the search and definition of citizenship beyond the family sphere and not through the family, while generational differences are mostly elaborated in the structure of the family and kinship unit.

Historical Change, Revolutionary Orientations, Generational Consciousness in Modern Youth Movements

The development in modern societies of such a dissociation between generations, and the concomitant possibility of the development of a special type of a distinct generational consciousness, is due not only to the complex division of labor that characterizes these societies. They are also closely connected to the relatively quick tempo of historical change, and above all to the consciousness of such change. Such consciousness is often connected with changes rooted in the revolutionary orientations that constituted important components of the construction of modern civilization, cultural values, and orientations. These revolutionary orientations were most fully articulated by the major social movements that have developed as part and parcel of modern life, of the constructions of modern social and political order, and of struggle around such construction. The possibility of the development of distinct generational consciousness has been enhanced in modern societies by the occurrence of rapid historical changes or ruptures, the consciousness of which is shared by members of the same age group or age cohort.

While historical change is particularly rapid and the consciousness of such change very widespread in modern societies, it does not always give rise to fully articulated generational consciousness – although to some degree such consciousness is probably rather common in modern societies and is not necessarily confined to the symbolism and ideology of youth. It is only in rather special historical circumstances and situations – like wars, changes of regime, and the like, especially of events that entail strong ruptures – that such generational consciousness has become articulated in modern societies in terms of youth symbolism.

Among such situations in modern societies, two are probably of special importance. One was developed at the end of the nineteenth and the beginning of the twentieth century, and found its fullest expression in the free German youth movements, although it was also present in the less spectacular youth movements of Central Europe and to some extent in the youth culture of various more flexible youth groups that developed in most modern societies. In all these movements, very strong attempts have been made to overcome the dislocation between personal transition and societal and cultural time. It was in them that dreams of a new life, a new society, freedom and spontaneity, a new humanity, and aspirations to social and cultural change found utterance. It was in these youth movements that the forging of youth's new social identity became closely connected with the development of new symbols of collective identity or new social–cultural symbols and meanings, which thus become foci of protest aimed at the reconstruction of society and culture.

While some of these orientations could be found in many of the youth groups that developed in most modern societies – be they in England or the United States – they developed most fully in situations where these groups became closely interconnected with major social movements oriented at the reconstruction of the centers and symbols of their respective societies. This was the case above all in the major nationalistic and revolutionary movements in Central and Eastern Europe, in Italy, Germany, Hungary, and Russia, or in the Zionist movement, where these orientations and student movements played a crucial role.

One of the major characteristics of many, probably most, of these movements was that in their ideology the symbolism of youth was very closely connected with that of the construction of new modern, especially national, collectivities that were being constructed at the period, and among the aims of these youth movements the reconstruction of such collectivities – national, social, or cultural – was central. These movements aimed at changing many aspects of the social and cultural life of their respective societies, to reconstruct the centers and premises of their respective societies in terms of some of the major revolutionary orientations of modernity. They depicted the present in a rather shabby light; they censured it for its materialism, exploitation, restrictive views, and lack of opportunity for self-fulfillment and creativity. At the same time they held out hope for the future – seemingly the not very far-off future – when both self-fulfillment and collective fulfillment could be achieved and the materialistic civilization of the adult world shaken off. They tried to appeal to youth to forge its own self-identity in terms of these new collective symbols, and this is why they have been so attractive to youth, for whom they provided a set of symbols, hopes, and aims to which to direct its activities.

The influence of such movements and orientations was very great, not only in political and educational but also in many cultural arenas. In a way, education itself has tended to become a social movement. Many schools and universities, and many teachers, have been among the most important bearers of collective values. The expansion of education itself is often seen as a means by which a new epoch might be ushered in.

Youth and Student Rebellion of the 1960s

The second historical situation in modern societies in which generational consciousness, couched in the symbolism of youth, became very prominent in the new social movements burgeoned in the late 1960s and early 1970s, and became most fully manifest in the various student rebellions and movements of the time.

The background to these new developments was a combination of the growing institutionalization of many of the collective values and symbols of the social, national, and youth movements discussed above, the rapid expansion of consumerism through easy credit and the continuous expansion of education and changes in occupational structure. These developments had several important repercussions on the organization of the life spans of youth.

The area of social life that the specific youth or student culture encompasses has tended to expand continuously. First, it has extended over a long period of life, reaching, through the impact of the extension of higher education, to what before was seen as early adulthood. Second, it tends more and more to include areas of work, leisure time activity, and many interpersonal relations. Third, the potential and actual autonomy of these groups, and the possibility their members have for direct access to work, marriage, and family life, to political rights, and to consumption, have greatly increased, while their dependence on adults has greatly decreased.

Paradoxically enough, the growing direct access of young people to various areas of life has given rise to a growing insecurity of status and self-identity and to a growing ambiguity of adult roles. This insecurity and ambiguity has been enhanced, first, by the prolongation of the time span between biological and social maturity and by the extension of the number of years spent in 'preparatory' (educational) institutions, and, second, by the growing dissociation between the values of these institutions and the future – especially in terms of occupational and parental roles – of those participating in them. A third factor is that for a long period many 'young' people may as yet have no clear occupational roles or responsibilities and may be dependent on their parents or public institutions for their economic needs, while at the same time they constitute an important economic force as consumers and certainly exercise political rights. In turn, this situation may become intensified or aggravated by the growing demographic preponderance of the 'young' in the whole population and by the increasing possibilities of ecological mobility.

All these developments gave rise to new types of generational and youth consciousness – a new combination between the symbolism of youth and collective symbolism. The older classical movements of protest and youth movements tended to assume that the framework and centers of the nation-state constituted the major cultural and social reference points of personal identity and of the charismatic orientations to some sociocultural orders, and that the major task before them was to facilitate the access of broader strata to these centers and full participation in them and possible changes in them. In contrast, the new movements of protest have been characterized by their skepticism toward these new modern centers and by lack of commitments to them – all of which denoted important aspects of what has been called by Weber the demystification of the world.

The foci of protest promulgated by these movements shifted from demands for greater participation in national political centers or from attempts to influence their socioeconomic politics to new directions. The most important of these directions were first, attempts to 'disrobe' these centers of their charismatic legitimacy and perhaps of any legitimacy at all; second, continuous searches for new loci of meaningful participation beyond these centers and the concomitant attempts to create new centers that would be independent of the existing center; third, attempts to formulate the patterns of participation in their centers not so much in sociopolitical or economic terms but more through symbols of primordial or of direct social participation.

These developments have often been connected with the breakdown of consciousness of historical continuity and of the conception of the future in terms of such continuity. The image of the societal future has become flattened and has been deprived of its allure. No sharp ideological discontinuity has been conceived between present and future.

Through these developments, youth has been, as it were, robbed of the full experience of the dramatic transition from adolescence to adulthood and of the dramatization of the difference between present and future. Their own changing personal future has become dissociated from any changes in their societies or in cultural activities and values. As a result of all these processes, the possibility of linking personal transition to societal and cosmic time – which was so strongly emphasized in the youth movements and observable also to some extent even in the earlier, looser youth culture – has become greatly weakened.

One of the most important results of these developments has been the evolution of a new configuration of youth symbolism and generational consciousness – the major characteristic of which was the creation of strong antinomian intellectual tendencies as a central component of such symbolism and consciousness.

It is not just the contents of these antinomian tendencies that are new, but the convergence of these contents with the spread and location of these movements. Of special importance in this context is the fact that this type of protest was not confined only to small, closed intellectual groups but involved widespread circles of novices and aspirants to intellectual status. Given the expansion of the modern educational system and the parallel effects of the spread of mass communication media, a very large part of the educated public have become aspirant to such status, and impinge on the centers of intellectual creativity and cultural transmission and become integral, even if transient, parts thereof.

This rather unique combination of intellectual antinomianism with youth rebellion gave rise to a new type of youth ideology that was connected to the reversal of the hitherto existing relation between the definition of different age spans and the possibilities of social and cultural creativity. Unlike in the past – even the not-so-distant past – youth became more and more seen not only as a preparation for independent and creative participation in social and cultural life, but as the very embodiment of permissive, often unstructured creativity – to be faced later on with the constants of a relatively highly organized, constrictive, meritocratic, and bureaucratic environment. Thus, youth in the late twentieth century became, even more than before, the transmitters and symbols of a continuous antinomian confrontation between the pristine values it embodies and a demystified social reality, and the impact of this new type of generational consciousness has been of crucial importance in the crystallization of what has been designated as the postmodern trend in contemporary societies. While the intensity and the concrete manifestation of this consciousness will

naturally change from one situation to another, the consciousness itself with the various antinomian tendencies analyzed above seems to have become more and more prevalent.

Conclusion: Generations, Politics, and Identity

In the contemporary world, generations continue to play a major role in shaping both domestic and international politics as seen with the so-called Arab Spring commencing in Tunisia in 2011 and then evolving into the 25 January Revolution in Egypt. Similar protest movements developed in Yemen, Libya, and Turkey. What these movements have in common is the presence of a large cohort of young people (typically young men) who have been relatively well educated but who cannot find adequate or rewarding employment in their own societies. Their frustrations and unrewarded expectations spilled over into collective protests against governments and their geriatric political leaders who were seen to be corrupt and unresponsive to their economic and social plight. The availability of online communication through Facebook and Twitter helped to forge global generational identities and consciousness (Alexander, 2011). There were some parallels between these youth rebellions in North Africa and the Middle East and the Occupy Wall Street protests of 2011 in New York and other major cities in the United States (Gitlin, 2012). While these political protests were contained, they indicate the ongoing relevance of generations to modern politics.

Generative Grammar

Manfred Bierwisch, Humboldt Universität Berlin, Berlin, Germany

Abstract

Generative grammar is the most influential linguistic theory of the last half century. Starting with the publication of Noam Chomsky's *Syntactic Structures*, it went through a number of stages, increasing the systematic insight into the structure of the human language capacity as a species-specific component of the biologically based cognitive endowment. The first stage proposed a system of levels that systematically characterize the formal properties of linguistic expressions. This system took up assumptions of American structuralism, turning it, however, into a complex theory of mental organization, which strongly contrasted with the behaviorist orientation of previous approaches of Bloomfield, Harris, and others. A characteristic feature of this stage was the central place assigned to the concept *grammatical transformation*, which for some time led to the identification of generative grammar with the more specific notion of transformational grammar. The second stage of the 'Generative Enterprise' was the so-called Standard Theory, according to which grammatical transformations relate two levels of syntactic organization of an expression, viz. its deep and surface structure, determining the semantic and phonetic interpretation, respectively. Further generalizations led to the third stage, called the Principles-and-Parameters Theory, which showed most of the properties accounted for by idiosyncratic syntactic rules to be derivable from quite general principles. This turned out to be a crucial change in theoretical orientation. Individual languages now seem to differ only with respect to lexical information and a restricted set of parameters to which the otherwise universal principles are sensitive. In subsequent stages of the so-called Minimalist Program, the language-specific principles of this theory are further reduced to general conditions of cognitive organization, leaving only a restricted set of formal features that account for the language-specific properties of the computational system that correlates invariant patterns of articulation with conceptually organized representations of experience, roughly sound and meaning. Generative grammar was from the very beginning one of the driving forces within the field of cognitive sciences, stimulating research in language production and comprehension, language acquisition, language change and typology, computational linguistics, neurolinguistics, and the biology of language, including the evolution of the language capacity. It has strongly influenced discussions in formal semantics and pragmatics, and the philosophy of language in general. A number of offsprings, such as case grammar, generalized phrase structure grammar, or lexical functional grammar, pursued issues in different though related ways.

Generative grammar is the label of the most influential research program in linguistics and related fields during the last half century. Initiated by a short book, Noam Chomsky's *Syntactic Structures* (1957), it became one of the driving forces among the disciplines jointly called the cognitive sciences. The term *generative grammar* refers to an explicit, formal characterization of the (largely implicit) knowledge determining the formal aspect of all kinds of language behavior. The program had a strong mentalist orientation right from the beginning, documented, e.g., in a fundamental critique of Skinner's *Verbal Behavior* (1957) by Chomsky (1959), arguing that behaviorist stimulus–response theories could in no way account for the autonomous and complex character of ordinary language behavior. The 'Generative Enterprise,' as the program was called in Chomsky (1982), went through a surprising development with remarkable changes and modifications, pursuing however the completely coherent and constant research strategy, attempting to characterize and to explain the properties of linguistic knowledge. Each stage of this research program extended, deepened, and simplified previous results and insights and was accompanied by consequences within the narrower domain of linguistics as well as the wider range of related fields, such as ontogenetic development, psychology of language use, problems of biological evolution, or philosophy of mind.

Transformational Structure and Levels of Description

The foundation of all further developments is to be found in the overwhelming monograph *The Logical Structure of Linguistic Theory* (Chomsky, 1975, henceforth LSLT), which was published only 20 years after the manuscript was completed. Starting from the notion of structural analysis as developed by Bloomfield and made precise by Harris (1951), LSLT introduces a radically new perspective on the nature of linguistic structure. On the one hand, LSLT takes up and systematically extends Harris's notion 'level of linguistic structure,' in terms of which the form of utterances, i.e., their phonetic shape and syntactic organization, is characterized. On the other hand, however, LSLT develops a notion of linguistic structure that differs fundamentally from the empiricist orientation of American structuralism. More specifically, Chomsky proposes a notion of grammar that provides a full and explicit account of the tacit knowledge a speaker/hearer has of the form of utterances of his or her language. Under this perspective, a grammar G characterizes the internal states of knowledge that relate only indirectly to the overt, observable behavior of the speaker. In other words, G is viewed as an empirical hypothesis about the mental structure underlying characteristic aspects of ordinary speech behavior. To make this view precise, LSLT highlights the importance of intuitive judgments a speaker is able to make about properties of utterances, such as the grammatical well-formedness of the famous

nonsense-sentence (1) as opposed to the ungrammaticalness of (2), or the rather different properties displayed by the superficially similar sentences (3) and (4), where (4) is deviant, even though one might make sense of it:

1. Colorless green ideas sleep furiously
2. Furiously sleep ideas green colorless
3. She is easy to convince
4. She is easy to be convinced

Hence G of English has to account for the properties on which intuitions like these rely. The study of the general features of G can furthermore be expected to reveal principles of the internal organization of mental states in general and of knowledge of language in particular. This is the reason for the impact generative grammar had on the neighboring fields.

More technically, LSLT gives an explicit formal account of two core notions of linguistic theory, viz. linguistic level and rule of grammar.

A linguistic level **L** is construed as an algebraic structure based on a set L of primes, in terms of which a set μ of so-called **L**-markers is constructed. The elements of μ exhibit **L**-specific properties and relations, providing, roughly speaking, the representation of linguistic expressions at the level **L**. The levels assumed in LSLT (following in part structuralist traditions) include the phonetic level **Pn**, the phonemic level **Pm**, the morpheme level **M**, the word level **W**, the level of word classes **C**, the phrase structure level **P**, and the transformational level **T**. For **Pm**, the set μ consists of strings of phonemes, for **W**, the elements of μ are sequences of words, and for **P**, the set μ consists of phrase markers, roughly tree structures indicating the constituency of an utterance. The relation between the different levels is anything but trivial and the topic of much further research. The complete structural representation of an utterance comprises the **L**-markers assigned to it at the various levels in question.

The rules of a grammar G consist of the conditions and operations that generate the expressions of a given language, together with their structural representations. Technically speaking, the rules of G determine for each level **L** the set of **L**-markers and the way they are related to the other levels. After a short account of phonological rules, defining the relation between the phonemic and phonetic level, LSLT deals extensively with phrase structure rules, generating phrase markers, and with grammatical transformations. They play in fact a central role in LSLT, such that for years the term 'transformational grammar' was taken as equivalent to 'generative grammar.' Transformations needed to capture central structural properties, which P-markers cannot account for. A simple case is shown in (5) and (6), which do not differ by constituency, but by their different transformational derivation, as informally indicated in (5′) and (6′):

5. this picture was painted by a real artist
6. this picture was painted by a new technique

5′. a real artist painted this picture == $T_{Passive}$ ==> this picture was painted by a real artist

6′. someone painted this picture by a new technique == $T_{Passive}$ ==>
this picture was painted by a new technique by someone == $T_{Agent\text{-}deletion}$ ==>
this picture was painted by a new technique

While phrase structure rules are based on a restricted type of formal operations, transformations are complex mappings, specified by pairs $\langle Q, t\rangle$, where Q is a structural index and t is a sequence of operations. Q determines the constituent parts an expression must exhibit for the elementary operations of t to apply to them. A feature that transformations in LSLT inherit from the kind of analysis proposed by Harris (1957), where transformations do not only relate individual sentences to their more elementary basis, as in (5′) and (6′), but are also used to explain the composition of complex sentences from their elementary parts, called 'kernel sentences.' Thus, e.g., (7c) is composed by embedding (7a) into (7b), replacing the bracketed pronoun:

7. a. this picture was painted by a new technique
   b. the director suspected [it]
   c. == $T_{Embedding}$ ==> the director suspected [this picture to be painted by a new technique]

Thus a distinction between simple transformations like $T_{Passive}$ and so-called generalized transformations like $T_{Embedding}$ must be made. Another problem was related to the distinction between obligatory and optional rules and the conditions underlying this distinction.

An important point of the framework developed in LSLT is the assumption that any linguistic theory must provide criteria determining the choice among different grammars of the same descriptive adequacy accounting for the same range of linguistic properties. To this effect, a simplicity metric is proposed which prefers a grammar that is simpler than its competitors if – but only if – greater simplicity corresponds to greater descriptive adequacy. Thus a grammar G that systematically accounts for the different properties of (5) and (6) is selected over a grammar G′ that can only assign to them the same constituent structure, even though G′ were formally simpler, as it is not descriptively equivalent. For this reason, a grammar with a transformational component could turn out to be more adequate than one without according to the simplicity metric, although it has more complex formal specifications. What is at issue here is not merely the general methodological maxim by which the simpler description is to be preferred; it rather concerns a substantive claim about linguistic knowledge, according to which the simpler grammar matches the way linguistic knowledge is spontaneously organized. This turns directly into an empirical issue with regard to the problems of language acquisition, i.e., the fact that each normal child acquires the notoriously complex knowledge within highly restricted limits of time and exposure. Facing this tension, the speculative answer given within the generative enterprise was right from the beginning the claim that the language faculty must provide the relevant structure as a biological endowment. To redeem this claim was a continuous stimulus of further developments.

The productivity of the proposed framework is demonstrated by the analysis of a large fragment of English with respect to phrase structure and transformations in LSLT and in a stimulating monograph on nominalization by Lees (1960). A seminal study of phonology is given in Halle (1959) for Russian and in Chomsky's unpublished master's thesis on the *Morphophonemics of Modern Hebrew*.

A characteristic feature that the Generative Enterprise can be said to inherit from American structuralism is the assumption that all grammatical structure, from the most concrete level **Pn** of phonetics to the most abstract level **T** of transformational structure, is a matter of linguistic form, which must be embedded in a wider context of semiotics that accounts for sense, reference, and use of linguistic expressions. Although there have been several proposals to include a level of semantics into the framework of generative grammar, the main emphasis was on the knowledge of linguistic form throughout.

The Standard Theory of Generative Grammar

Immediately after the publication of *Syntactic Structures* (actually lecture notes excerpted from LSLT), the theory it proposed attracted interest from various sides, including notably mathematical linguistics and psychology. An overview of formal properties of grammatical rules, especially of phrase structure grammars, in Chomsky (1963) established what became known as the Chomsky hierarchy of formal grammars as a branch of subrecursive function theory. Miller and Chomsky (1963) gave a first outline of the role of generative grammar in the study of language comprehension and production. Furthermore, Katz and Fodor (1963) made a first proposal to extend the theory of grammar by a semantic component, using so-called projection rules to compositionally integrate the meaning of lexical items according to their syntactic relations.

The main development, however, was due to continuous efforts to systematically constrain and strengthen the theory, increasing its explanatory power by reducing the range of possible grammars compatible with a given set of data, as each systematic step to that effect decreases the task of the evaluation metric. Efforts to this effect led to what was later called the 'Standard Theory' of generative grammar. Based on preparatory ideas discussed a.o. in Katz and Postal (1964), this is formulated in Chomsky's *Aspects of the Theory of Syntax* (1965). At its core is a reassessment of the nature of transformational structure. Instead of a separate level **T** of transformations, grammatical transformations are now construed as operations that derive the relation between two levels of syntactic representation, both of which are characterized by P-markers. This modification is related to one of the most influential distinctions proposed in the Standard Theory, viz. that between *deep structure* and *surface structure*. On this view, each sentence exhibits a deep and a surface P-marker, with transformations deriving the latter from the former. Thus except for the different choice of personal or wh-pronouns, (8)(a)–(d) are just different surface realizations of the same deep structure, where the bracketed Agent phrase might furthermore optionally be deleted by $T_{\text{Agent-deletion}}$, known from (6′).

8. a. John may expect someone to convince her
   b. someone may be expected by John to convince her
   c. who may John expect someone to convince
   d. who may be expected by John to be convinced (by someone)

On this account, the semantic interpretation of linguistic expressions seems to be determined by their deep structure, which would be an interesting step toward an integration of the grammar into an account of meaning and reference. Another important aspect of the Standard Theory is a more systematic distinction between (1) the lexical system, i.e., the complex system of rules providing lexical items with their (idiosyncratic) phonetic, syntactic, and semantic properties, and (2) the grammatical rules that integrate the lexical information into the structure of complex linguistic expressions. Altogether, a more perspicuous design of the components of grammar and their relation to the levels of structural representation appears to emerge, compared to the system assumed in LSLT. The syntactic levels that seem to be crucial are deep- and surface-structure, while word- and morpheme-structure do not have an independent status. The components of the grammatical rule system are (1) the base component, including the lexical system and the phrase structure rules, (2) the transformational component, (3) the phonological component, and possibly (4) the semantic component. Rules and representations are interrelated according to the schema in (9), with levels of syntactic representation underlined:

```

The base component and the transformations together constitute the syntactic component.

The semantic component raises problems to be taken up below, while the organization of the phonological component, extensively discussed in Chomsky and Halle (1968), is assumed to have a fairly clear organization, parallel to that of the syntactic component in relevant respects. The underlying phonemic structure, made up from the phonological features of lexical items, is similar to deep structure

with phonological rules deriving the phonetic surface organization:

10. $\underbrace{\underline{\textit{Phonemic Structure}} \Rightarrow \text{Phonological Rules} \Rightarrow \underline{\textit{Phonetic Structure}}}_{\text{Phonological Component}}$

Remarkably simplified is especially the form and function of grammatical transformations. Thus generalized transformations are completely dispensed with, as the recursive deep structure of complex sentences is generated already in the base component. A particularly elegant feature that emerges from this reorganization is the principle of cyclic operation of the rules, which is added to the assumption already made that rules are ordered with regard to their application. The problem that immediately arises is the distinction between extrinsic (i.e., stipulated) and intrinsic ordering, the latter emerging from independent properties of rules and their organization. Cyclic operation apparently captures a central property of natural languages: the same sequence of operations applies to increasingly larger parts of an utterance, defining its syntactic properties, its phonetic patterns, and the compositional integration of its semantic structure.

An important general effect of the Standard Theory is the perspicuous account it suggests for the traditional notion of linguistic universals, or universal grammar (UG), considered as the innate, biologically fixed structure underlying the species-specific language capacity. The range of possible rules and the architecture of their interaction, as schematized in (9) and (10), could now be construed as formal universals, the potential primitive elements entering the rules and representations as substantive universals. Under this perspective, the set of possible grammars G accessible as instantiations of UG determines the diversity and typological differentiation of possible natural languages, including the range of variation delimiting processes of linguistic change. By the same token, UG provides the innate, formal basis and predisposition that makes language acquisition possible. These accompanying considerations of the Standard Theory led to a new, principled approach to problems of language acquisition, as well as linguistic change.

Extensions and Modifications of the Standard Theory

Shortly after the Standard Theory was formulated, empirical analyses as well as efforts to improve the structure of the theory led to proposals modifying the model. Controversial arguments concerned the role of semantics as indicated in (9). Lakoff (1971) and others proposed a model, according to which semantic representations are the underlying structure of linguistic utterances, from which surface structures are derived step by step by means of transformations and lexical rules. The insights and difficulties created by these proposals triggered a counterproposal, called the Revised Standard Theory. On the basis of observations discussed in Jackendoff (1972), it became clear that meaning is not unaffected by surface structure phenomena. For example, (11) and (12) rely on the same deep structure, with passivization applying to (12) but not to (11), but they do not in general have the same meaning:

11. Three students in the class wrote only one paper
12. Only one paper was written by three students in the class

Due to what is called the scope of quantification, in (11) the restriction of having written one paper is ascribed to three students, while in (12) the restriction of being written by three students is ascribed to a single paper. While (11) does not decide whether the students jointly or individually wrote one paper, the latter option is practically excluded in (12). As phenomena of this sort are by no means marginal, the Revised Standard Theory recognized a more complex relation among syntax and semantics than that indicated in (9). Certain aspects of meaning are determined by deep structure, while scope and certain other relations depend on surface structure, such that transformations – contrary to the Standard Theory – might still affect the semantic interpretation.

A technical way to handle these problems is the so-called Trace Theory proposed in Fiengo (1977). According to this proposal, a constituent that is moved, i.e., reordered, by a transformation leaves behind a trace that is phonetically empty, but may play a role in semantics, as indicated in (13), where e_i is the trace left in the initial position of the co-indexed pronoun *who*:

13. who_i do you want to talk to e_i

In many cases, the trace turns out to be similar to what logicians consider a variable bound by the operator contained in the moved constituent. In this sense, invisible elements of the surface structure account for its contribution to semantic interpretation. Other types of empty elements of the surface structure are 'invisible' pronouns, as in (14) (a) and (b), where the actor of the infinitive clause is controlled by (i.e., coreferential with) different constituents of the main clause:

14. a. John_i promised Mary [e_i to take the train]
    b. John recommended Mary_i [e_i to take the train]

Now, representations like those in (13) are based on transformations and cannot therefore belong to the pretransformational deep structures of (9); but they cannot belong to the surface structure either, as they contain abstract elements like traces and empty pronouns, which don't have phonetic realization. To reconcile these problems, a reorganization of linguistic knowledge has been considered, providing a more abstract syntactic representation called S-structure, on which the semantic as well as the phonetic interpretation can depend. Thus (9) would have to be replaced by the schema sketched in (15), where the Logical Form LF is the place of all the information by which G determines the meaning of an expression, just

as the Phonetic Form PF specifies the conditions G imposes on its pronunciation:

15.
```
      Syntax
        |
  S-structure
    /     \
  PF       LF
```

The Trace Theory furthermore plays a central role for more general conditions by which transformations and their effects are constrained. Thus in cases like (16)(a), where the subject of the embedded Verb Phrase *take the train* ends up as the pronoun *who*, this relation is mediated by a chain of positions as marked in (16)(b). This chain is created by the cyclic application of one operation to a single constituent along the recursive embeddings indicated in (16)(b), as the deficiency of (16)(c) strongly suggests.

16. a. Fred knows who John might persuade to be ready to take the train
    b. Fred knows [who$_i$ John might persuade e_i [e_i to be ready [e_i to take the train]]]
    c. Fred knows [who$_i$ John might persuade him$_k$ [e_k to be ready [e_i to take the train]]]

Observations like these entered the more general endeavor initiated in Ross (1967), to heavily reduce the complexities of the structural index Q and the possible operations *t* of transformations. In this way, transformations are eventually to be reduced to one general operation '*Move* α,' where α is any constituent, all further constraints deriving from principles imposed by UG. These general principles also include a systematic simplification of phrase structure rules in terms of so-called X-bar structure. This structure takes up a proposal made already in Harris (1951), according to which phrase structure combines syntactic constituents X and Y to form a complex constituent $\bar{X}$ with X as its dominating head. In somewhat simplified terms, the properties of $\bar{X}$ (e.g., *drink wine*) are determined by its head X (viz. *drink*), where Y is either a selected complement of X, as in *drink wine*, or a free adjunct, as in *drink slowly*. The selectional properties of X make up its lexically determined Argument-Structure, called Thematic Grid, an important syntactic aspect shaping the semantic interpretation such as <Agent, Theme> for the verb *drink*.

All these modifications of the Standard Theory were motivated and supported by descriptive problems, arising from a wide range of well-known as well as unrecognized facts; at the same time, however, they were driven by the central aim to restrict the wide range of possibilities UG provides, thereby strengthening the explanatory capacity of the theory.

The Principles-and-Parameters Theory

A major breakthrough in this direction was achieved by the so-called Principles-and-Parameters Theory, formulated in Chomsky's *Lectures on Government and Binding* (1981). The basic idea of this new framework is to dispense with the notion of UG as a rich system of different types of rules, individual grammars must be made up from, relying instead on a restricted system of universal principles that constrain the effect of a few basic operations including *Move* α and the schema of X-bar theory, generating and interrelating representations according to the basic architecture indicated in (15). The principles in question specify the conditions these general operations are subject to, determining, e.g., the relation between the positions of moved constituents as in cases like (13) or (16), specifying the features that candidates of possible movement must or must not exhibit or the conditions that trigger the operation in question, and a fair range of further intricate properties. These principles constitute separate subsystems of linguistic organization, such as the Theory of Government, of Binding, of delimiting Boundaries, of Control, of Case-features, and the effect of Thematic roles. Presupposing the levels indicated in (15), the components of a grammar G in the framework of Principles-and-Parameters can roughly be indicated as follows:

17. a. Lexical system, fixing the idiosyncratic phonetic, semantic, and syntactic properties of lexical items
    b. Syntactic operations:
       X-bar syntax,
       Move α
    c. Principles of Government, Binding, Bounding, Thematic structure, Control, and Case-Assignment
    d. PF-component (assigning phonetic interpretation)
    e. LF-component (adjusting to referential and conceptual conditions)

Extensive studies dealt with further consequences of this framework, such as Kayne's (1984) exploration of general properties of phrase structure or Rizzi's (1990) clarification of more specific conditions on movement operations, among a wide range of other work.

Two important points of this conception must be emphasized. First, the systems of principles in (17)(c) are essentially different from the grammatical rules assumed in the Standard Theory: while rules were supposed to be necessarily different for different languages, the principles of Government, Binding, Case, etc. are construed as providing the universal organization of the language capacity; in other words, they are not elements of particular grammars, but are part of UG. Hence they are not subject to language acquisition, but are part of the biological endowment. Second, the obvious structural differences between different languages are no longer conceived as consequences of intricate systems of different rules. They are rather explained by a restricted set of parameters contained in the general principles, to which particular languages can assign different values. For instance, the head X of a constituent $\bar{X}$ may be in the initial position of $\bar{X}$, as in *drink wine*, or in the final position, as in German *Wein trinken*, depending on the so-called head-parameter, or the interrogative pronoun can be required to be moved to the clause initial position, as in English, or stay *in situ*, as in Japanese, etc. Most (or all) of these parameters seem to be related to classes of particular lexical items, so that all language-particular properties are basically related to lexical information.

This leads to a rather different view of how UG determines an individual grammar G. Besides lexical items making up the language-particular dictionary, grammars of different languages might differ only by their choice of parameter values,

while the principles presupposed by these parameters are given by UG and hence identical for all languages. Under this perspective, language acquisition consists essentially in identifying the lexical system of a language, thereby fixing also the particular values of the parameters contained in UG. This must not be misconstrued as reducing the importance of the implicit knowledge of G: the very essence of the language faculty is its combinatorial capacity.

These observations relate to one of the core issues of generative grammar, called the logical problem of language acquisition. This problem concerns the need to explain the surprising fact that the organism normally develops an appropriate grammar on the basis of rather restricted, deficient, and partially corrupt evidence which the child is normally exposed to. This problem could not seriously be approached, if UG were as unconstrained as the Standard Theory would have to assume, providing all the options the unconstrained transformational component would allow for. As a matter of fact, much of the overwhelming capacity of the Standard Theory is to be dispensed with, because on closer inspection complex operations such as passive transformation or relative clause formation usually had to be reduced to the combination of more elementary operations such as *Move* α under general constraints. Thus the Principles-and-Parameter Theory is an important step toward an explanation of the human language capacity.

In view of the continuous modification and improvement of generative grammar, the shift to the Principles-and-Parameters conception is certainly the most important change. The preceding concepts and changes can be considered as preparing the present model, which the following changes and amendments unfold and develop. Based on the instruments and tools explored so far, it is now the type of problems and the kind of explanation to be developed which come into focus.

Among the numerous stimulating consequences of this model is a new perspective on historical and typological variation. Like language acquisition, linguistic change and typological differences are not only constrained by UG, but also closely related to the options provided by the parameter values on the basis of universal principles.

The Minimalist Program of Generative Grammar

Taking the Principle-and-Parameter Theory as a starting point, a new phase in the Generative Enterprise, called *The Minimalist Program*, was initiated in Chomsky (1995). Striving, as before, for an explanatory account of the Language Faculty, two different though interrelated issues are systematically explored within this program. One of these issues goes on to reduce the rules and processes of the computational system of language to more basic operations, with the reduction of grammatical transformations to the simple operation *Move* α serving as the first programmatic step. In the same spirit, the whole X-bar syntax, i.e., the residue of the system of phrase structure rules, is now reduced to one single operation *Merge*, which just combines two syntactic objects X and Y into one unit Z, automatically turning the head of X or Y into the head of Z, requiring the selectional features of the head to be saturated, determining at the same time the categorial properties of Z. In a way, *Merge* includes a highly restricted version of generalized transformations, insofar as both X and Y may be the result of previous merging. On this background, the next important simplification comes as a natural step: *Move* α can be construed as the operation that takes up α and copies, or rather remerges, it at a predetermined position, usually the edge of the domain on which *Move* operates. In other words, *Move* turns out to be just another instance of *Merge*, which does not add a new element, but reassigns an already merged element on a new position. This so-called 'internal Merge' recombines an element, in contrast to ordinary 'external Merge,' which adds new material. In any case, the generative system reduces to the recursive application of *Merge*, with the various systems of (parameterized) principles and conditions controlling its effects.

The computational system underlying the knowledge of language can thus be construed as a single recursive operation that recruits for each expression E a number of lexical items N (a so-called Numeration) to combine them – constrained by the parameterized principles of UG – into the complex linguistic structure of E, as schematized in (18), where |UG| abbreviates the principles of UG with the parameters fixed, and E provides the PF and the LF of the expression.

18. N === *Merge* ===> E
⇑
|UG|

The second issue pursued in the Minimalist Program concerns the possibility to derive the principles of UG as far as possible from more general (possibly language independent) conditions of cognitive organization plus the boundaries that are conceptually necessary to constitute the domain of linguistic knowledge. Minimal assumptions require linguistic expressions to compositionally relate sound and meaning, or more technically to determine a systematic correspondence between patterns originating from the perceptual and articulatory system A–P, i.e., the sound structure of E, and representations in the range of conceptually and intentionally organized experience C–I (the conceptual–intentional (system)), roughly the overall domain of thought. This requires the internal or I-language to provide a compositional correspondence of PF and LF as the interfaces, in terms of which a linguistic expression E relates to or interacts with A–P and C–I, respectively, as sketched in (19):

19. signal <===> A–P ⇔ PF ←--→ LF ⇔ C–I <===>
environment

Hence, a grammar G determines a pair $<\pi,\lambda>$ for each linguistic expression E, with π a representation in PF and λ a representation in SF and E is derived from a numeration N of lexical items according to (18). Now, the research strategy of the Minimalist Program proposed in Chomsky (1995) and elaborated in Chomsky (2000, 2002) explores the possibility to derive the properties of UG as far as possible from these minimal assumptions together with the hypothesis that UG is subject to conditions of structural economy. To this effect, lexical items selected by a numeration N must be supposed to contain all and only the idiosyncratic specifications by

means of which the elements of N participate in computation of the pair <π,λ>. Besides the phonetic and semantic features to be interpreted in the extralinguistic domains P–A and C–I, respectively, these specifications include certain grammatical or formal features controlling by means of agreement, Case-selection, and other grammatical requirements the purely language internal computation of <π,λ> from N.

Two types of very general conditions are supposed to influence the computation of linguistic expressions, called full interpretation (FI) and shortest derivation (SD). As to FI, the ultimately derived interface representations must be appropriate to the interpretive substance of their respective domains. This means that representations in PF and SF must not contain uninterpretable, vacuous elements or formal features and configurations that cannot be interpreted in P–A and C–I, respectively. This requires formal features to be eliminated on systematic grounds in the derivation of PF–SF pairs, otherwise the resulting expression is not well formed, i.e., ungrammatical. As to SD, the admission of internal *Merge*, that is the movement of elements already merged, does on the one hand extend the derivation of E from N beyond the quest for the smallest number operations, but it allows on the other hand grammatical operations to delete uninterpretable features by meeting, e.g., agreement conditions, thereby avoiding violations of FI.

The intricate interaction of conditions and features on which these operations depend seems to proceed stepwise, barring movement of constituents and matching of features, once the PF-representation is spelt out, i.e., has access to phonetic interpretation. Thus the schema in (18) would have to be modified as in (20), assuming that Merge proceeds in what has been called phases, namely combining elements from N, until a unit with certain properties (presumably some kind of propositional completeness) is reached and the next phase can start, until N is exhausted – a procedure that takes up the cyclic operation of the Standard Theory.

20. N ====> *Merge* ====> LF
⇓
Spell out
⇓
PF

The requirement of FI presupposes external and internal *Merge* to check and eliminate step by step the formal features, leaving only information that can appropriately be interpreted in terms of articulatory and conceptual conditions at the two interface levels. A remarkable range of facts in different languages has been shown to follow from appropriate lexical information together with minimal assumptions about *Merge*, *Move*, plus the two sorts of general conditions regulating the economy in representation and derivation.

A specific issue raised by the Minimalist Program is the question whether the design of the computational system of language is optimal, given the external conditions A–P and C–I noted in (19) and the plausible requirements of FI and SD. With respect to this question, it is a peculiar fact about natural languages that the derivation from N to <π,λ> cannot in general be restricted to the simplest possible option, requiring only the operation of simple, external *Merge*. The language capacity obviously exploits freely the effect of what was called *internal Merge* (or *Move* α), using 'displaced' constituents as borne out even by simple cases like *Who*$_i$ *did he talk to* e_i. It is an interesting but undecided question whether this obvious deviation from what would be the apparently optimal design is still in line with the most efficient way to establish the correspondence between PF and SF – as it might in fact be the case, if different relations within distinct aspects of C–I would have to be captured. Two things must be emphasized in this respect. First, considerations like these (and in fact the Minimalist Program as a whole) go beyond just methodological concerns, following only the usual concern for the simplest possible theory, but have to do with the subject matter as such, namely the organization of the language faculty. The Minimalist Program raises the question: How far does the computational system of the language faculty represent the optimal solution for the task of relating the two heterogeneous interfaces LF and PF? To clarify and motivate the specific details of the pertinent operations, different proposals are intensely explored, e.g., with respect to the features that categorize the different combinations built up by Merge. Second, these matters make sense only to the extent to which conditions based on C–I (that is on structures of thought or meaning) are taken as seriously as questions arising from A–P. As a consequence of the symmetry inherent in the design noted in (19), the Minimalist Program made the relation to standard views of semantics more explicit. Semantics is usually concerned with truth and reference, construed as relations of expressions to the environment, i.e., to external objects and states of affairs. In contrast to that, Chomsky (2002, 2012) argues strongly that these relations are barely accessible to scientific investigation. Even standard examples like '*water* refers to H_2O' are spurious in view of what is actually known about the structure of the relevant molecules and the use of items like *water*. Discussing a wide range of similar problems, Chomsky notes that the remarkable insights, which semantics nevertheless provides, do not really deal with the relation of expressions to the environment, but with the structure of LF and its relation to C–I as sketched in (19), with lexical items referring not to external entities, but related to concepts and their combinations. Under this perspective, LF concerns the formal structure of meaning, the 'content' of which is its conceptual interpretation in C–I, and Chomsky notes that syntax to a large extent is concerned with problems that are usually considered as semantics. This clarification does not only rationalize and slightly reduce the skepticism with respect to semantics noted in the beginning, it also widens and delimits the perspective of generative grammar.

It is to be noted that, from this point of view, the species-specific language capacity might essentially consist in the availability of discrete infinity and in fact be related, as Chomsky (1982) speculates, to the computational capacity underlying arithmetic. The language capacity clearly recruits and enhances general cognitive and communicative capacities, but its evolution, which Pinker (1994) persuasively argues to be due to adaptive selection, might well be an independent step accompanying evolutionary changes in the architecture of the human brain.

As a final example for the continuous extension and modification the Minimalist Program pursues, the interest in what Chomsky (2005) calls the 'third factor' will be mentioned. According to assumptions explored in the generative enterprise, two different factors are involved in the genesis of the internal

language: (1) the biological basis, characterized by UG and anchored in the genome, and (2) experience, i.e., the data the child encounters. To these conditions, those of the third factor have to be added. They comprise principles not specific to the language faculty, viz. principles of data analysis, of structural architecture, of organic form and action, of efficient computation, and they are based in part on overall conditions of physical organization, as should be expected, if language is a natural phenomenon.

General Perspectives

The intellectual force of generative grammar comes from the combination of two equally important factors. First, it provides a suggestive methodological and theoretical perspective for the study of language as part of the biological endowment of the human organism, supporting a central system of the overall cognitive capacity; second, it shows how this perspective can be made precise, turned into an effective research program, and pursued with respect to a large domain of empirical facts not recognized before. It is indeed the wide range of phenomena – from syllable structure and inflection to quantifier scope, focus determination, and syntactic embedding – as well as the diversity of languages – from English, German, and Chinese to Hebrew, Malaialam, and Walbiri – that gives the Generative Enterprise its unusual place in the field. The explicit formulation of the theory, its technical means, and its cognitive orientation are the reasons for its strong impact on a wide range of subdisciplines, from research in language comprehension and production, acquisition, and aphasia to typology, historical linguistics, computer science, poetics, theory of music, and philosophy of language.

During the stages sketched in (1)–(5), various offshoots have developed different, though related, ideas. These are a.o. categorial grammar, dependency grammar, case grammar, lexical functional grammar, generalized phrase structure grammar, head-driven phrase structure grammar, and relational grammar, to mention the more influential proposals. Another type of offspring is optimality theory, which – starting from a different background – develops certain ideas of the Minimalist Program in a different way, assuming that conditions on linguistic structure may be of different strength and can be violated.

A peculiar relationship must finally be noted between generative grammar and the various theories of semantics and pragmatics. Sticking to the initial notion that grammar can and must account for the structure, but not properly for the complexities of interpretation and use of language, Chomsky did not extend his theory of language to the domain of semantics and pragmatics. It might be noted, in this connection, that he essentially considered LF as a syntactic level, pertaining to the form, rather than the interpretation of language. Therefore, Formal Semantics as developed by Montague (1974), Discourse Representation Theory as proposed by Kamp in Kamp and Reyle (1993), Speech Act Theory as conceived by Searle (1969), and a fair number of related approaches to aspects of interpretation and use are compatible with and in part stimulated by generative grammar, but they have not been included within its proper domain. Even though this skeptical delimitation of the field was occasionally met with disappointment, it could not really diminish the intellectual attraction exerted by the Generative Enterprise – and has moderately been relativized by the needs of the Minimalist Program.

Genes and Behavior: Lessons from the Fruit Fly

Ralph J Greenspan, University of California, San Diego, La Jolla, CA, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Behavior draws on the activities of a wide range of genes acting at many different times in an individual's life. Model organisms have provided insight into the role of genes in behavior that have major implications for humans. Many of the mutations and genetic variants (alleles) that affect behavior in the fruit fly *Drosophila* have proved to be subtle changes in genes that, when more severely mutated, produce wider ranging effects. These studies based on model organisms have also provided information on the circuitry underlying behavior. Their study has made major contributions to our understanding of innate and learned behaviors, and points to the importance of network interactions among genes as well as among neurons in producing behavior.

Introduction

The idea that behavioral traits are passed from one generation to the next is an ancient one. Humans have acted on it for centuries in the breeding of domesticated animals and have assumed that it accounted for much of our own behavior as well. With the advent of the science of genetics, the question of how genes influence behavior has been recast as to which genes influence a given behavior and how they influence it. For humans, the question of the nature and extent of genetic influences on behavior is still hotly debated, and little is known about the latter question of mechanism. Still unresolved is the issue of how to unravel the interactions between genes and the environment in human affairs. There is no question that all behavior is affected both by genes and the environment in animals and in humans, and our ability to dissociate the two in humans is inevitably limited. However, because laboratory animals are raised under conditions where environmental differences between individuals can be minimized, the study of genetic influences on behavior can be focused on more sharply.

The principal lessons from such animal studies are that the relationship between genes and behavior is a complex one: multiple genes contribute to each aspect of behavior, and each gene participates in multiple aspects of behavior. Behavior is an emergent property of the organism's many interacting systems. Genes encode proteins, proteins build the constituents of cells, cells form the nervous system and other organ systems, and the nervous system ultimately gives rise to behavior. Thus, genes can affect behavior by participating in all the major kinds of biological processes – development, physiology, and the biochemistry of intracellular signaling. We will examine examples of such genes in the organism for which the most is known, the fruit fly *Drosophila melanogaster*. The value of a model system, however, must be more than its experimental versatility; it would be of no help if the phenomena and principles are fundamentally different from those of humans. Fortunately, they appear to be similar by an ever increasing number of criteria. One of the most striking outcomes of modern biology and the sequencing of genomes is the similarity of genes between distantly related creatures. The fruit fly *D. melanogaster* and humans share roughly two-thirds of the same genes in common. Similarly, they share considerable conservation of metabolic and signaling pathways at the cellular level. Most strikingly, and most relevant for this discussion, there are also specific instances of conservation at the level of behavior and its molecular mechanisms.

From Single Genes to Many

The earliest studies of the connection between genetics and behavior date back to the dawn of animal genetics, and were mainly directed at testing whether behavioral traits showed the same propensity to Mendelian inheritance as did physical traits.

Tropisms

The fruit fly, *D. melanogaster*, made its research debut in the laboratory of William E. Castle at Harvard University in 1901, the first laboratory to pursue the newly propounded principles of Mendelian genetics in animals, concentrating primarily on the coat color genetics of guinea pigs and rats. However, mammalian breeding studies take up a lot of laboratory space and at least four to five weeks per generation. So Castle took the suggestion of his entomologist colleague C.W. Woodworth and began working with the faster breeding fruit fly, testing how well it tolerated inbreeding and selection, and probing some of its simple behavioral responses to light (phototaxis), gravity (geotaxis), and odors. These responses are known as tropisms, the innate tendency to move toward or away from a particular stimulus, such as light, gravity, heat, or an odor.

None of these behavioral studies involved the use of genetic variants, and one may wonder where the idea came from to look at these behaviors. The most likely influence was the German zoologist Jacques Loeb who had moved to the United States and became a key figure in establishing the University of Chicago as one of the first research universities in America. Loeb's research on tropisms in flatworms was well known to all zoology students, and is referenced in these early *Drosophila* papers. A decade later in T.H. Morgan's fly laboratory, R.S. McEwen was the first to show that a mutant (i.e., a strain of flies in which an allele is drastically altered in comparison to those usually found in natural populations), the body color mutant

tan, was defective in phototactic behavior (we now know that this gene encodes an enzyme for pigment synthesis that also affects synthesis of the neurotransmitter histamine, which is released from the photoreceptor cells). In the 1950s, Jerry Hirsch had taken up this neglected field and shown that fly behavior could be dramatically altered after selective breeding for divergent phototactic or geotactic behavior (Hirsch, 1959). Hirsch's work was directed at showing that behavior has a basis in heredity, but his flies could not be further analyzed for which genes were responsible, let alone the mechanisms responsible.

A new angle on the role of genes in behavior emerged in the 1960s, growing out of the successful studies on the molecular genetics of bacteria and viruses. The microbial studies had yielded basic principles about the molecular nature of the gene, and had also established basic strategies for using genetics to analyze biological processes. One strategy is to detect individual genes essential in a process by inducing and isolating mutants that show specific defects in that process. The identities of the affected genes then give an outline of the actual 'steps' in the process. Another strategy uses altered genes of known function as tools to disrupt a process at specific points.

Armed with these strategies, one of the premier practitioners of microbial genetics, Seymour Benzer, inaugurated a new approach to the study of behavior using genetics in the fruit fly *D. melanogaster*. His aim was to 'dissect' behavior into its component genetic parts. At the time, all that was known with any certainty was that genes encode proteins, with little idea of what the genetic mechanisms of behavior might be. Ideas ranged from one gene per synapse to one gene per behavior. The primary focus was on the role and importance of single genes, but researchers also began early on to use genetic tools to identify portions of the nervous system relevant for particular behaviors. This latter work served as a precursor to today's emphasis on identifying the circuits underlying behavior.

Benzer began with phototaxis, as did Castle 60 years earlier, isolating many nonphototactic mutants. The outcome was not tremendously encouraging, as they were mostly blind mutants, which offered minimal insight into the mechanisms underlying a tropism. A few, however, did provide a window into brain mechanisms of visually driven behavior (see Section Anatomical Mutants, below). But Benzer and his students did not limit their efforts to phototaxis, and soon expanded into more interesting fly behaviors.

Complex Innate Behavior

Tropisms are not the only innate behaviors that flies do; there are also social behaviors that do not require learning or experience, of which courtship is probably the most elaborate. As the activity that accounts for most of their social life, it is rich in content, complex in elicitation, and robust in execution. One must practically hit the fly over the head, genetically speaking, to keep it from courting. Consistent with this picture, a male fly is fully capable of performing the entire courtship sequence in all its aspects even if raised in complete isolation from egg to adult and then presented with a virgin female as his first encounter with another creature. As an essential piece in the fly's evolutionary repertoire, it is not surprising that reproductive behavior should be reinforced and buffered against random events, whether developmental or experiential, that might subvert it.

Male flies must go through a ritual set of actions before a female will be receptive to mating. Female courtship behavior has no overt actions and consists primarily of allowing the male to mate. It has thus been studied far less. When a male encounters a female, he will orient, stand facing in her direction about 0.2 mm away (flies are 1.5 mm long), tap her on the abdomen with his foreleg, follow her if she walks away, and then extend one wing and vibrate it to produce a 'love-song'. Depending on the female's level of interest at this point, he may go back and repeat these actions or he may go on to the next stage, in which he extends his proboscis and licks the female's genitals (Figure 1).

Figure 1 The sequence of behaviors in heterosexual courtship of *Drosophila melanogaster*. Reprinted from Greenspan, R.J., 2007. An Introduction to Nervous Systems, Cold Spring Harbor Laboratory Press, Cold Spring Harbor, NY: pp. 111, Figure 7.5. Copyright 2007, with permission from Cold Spring Harbor Laboratory Press.

He then may go on to mount her and, if she is receptive, copulate. Female fruit flies will not mate unless the males have gone through this routine and the female has become receptive.

Sex-specific behavior in the fruit fly world is as much a part of the genetic difference between males and females as appearance and reproductive physiology. In flies, each cell determines its choice of sexual phenotype independently, based on its chromosomal makeup – one X for male and two Xs for female in normal diploid flies. This sets off a cascade of sex-determining genes that produce the various differences, or dimorphisms. In the cells that are precursors of the gonads, this genetic cascade produces the appropriate genitals for each sex. In the brain, it produces the circuitry for sex-specific behavior.

A gene called *fruitless* is essential for much of this male-specific development (Ryner et al., 1996). The gene encodes multiple forms of a transcription factor, one of which is male specific. In males that are missing the male-specific product, courtship does not occur. Conversely, when this male-specific product of the *fruitless* gene is expressed in a developing female brain, the adult female will perform malelike courtship behavior, which is never otherwise seen in females (Stockinger et al., 2005). The male-specific product of the *fruitless* gene is expressed in most of the brain regions shown to undergo sex-specific development for courtship, and this male-specific product appears to do little else apart from governing sex-specific development in the male nervous system (Figure 2). Other gene products from the same locus, which are not sex-specific, have more vital functions.

The *fruitless* gene's specificity would seem to belie the earlier claim about the relationship between genes and behavior being complex, but in 50 years of fly behavior mutant hunting, it is the only example of its kind. All other genes in which behavioral mutations have been found are notable for affecting many different phenotypes (technically referred to as 'pleiotropy'). Instead, the specificity of those mutations comes from the restricted nature of the mutation's effect on the gene's expression or activity (Greenspan, 2001).

Plasticity and Learning

Fruit flies can be trained to remember, to learn to tell the difference between smells or between things they see. If an odor (or image) is accompanied by an electric shock or a heat lamp, flies quickly learn to avoid it; the memory of this association will last for a day at most. What does it take to get them to remember it for longer? Regular conscientious practice (just like your piano teacher may have told you). In other words, as any student knows, cramming for an exam (i.e., all the training at once), can get you through the next day, but it does not stick. Studying at regular intervals, on the other hand, produces a much longer lasting memory. Fruit flies are no different. If multiple training trials are delivered all at once, memory still only lasts for a day. However, if the training trials are interrupted with 15-minute rest intervals, then the flies will remember it for up to a week. This is a substantial portion of a fruit fly's lifespan – midlife crisis has already set in by their second week of adulthood.

The first two genes identified from screens for learning and memory defects uncovered two components of a cyclic adenosine monophosphate (cAMP) cascade: *dunce* encodes a cAMP phosphodiesterase and *rutabaga* encodes a type I Ca^{2+}/calmodulin-stimulated adenylyl cyclase. These are two components of the same cascade that serotonin acts upon in the gill withdrawal reflex. Furthermore, cyclic AMP response element binding (CREB) turns out to be just as important in flies as in sea snails: flies with deficiencies of CREB also have poor memory (Yin et al. 1994). The cAMP pathway acts in mammals as well as in invertebrates; mutations in CREB, for example, alter memory in mice, and there is a human mental retardation syndrome due to mutations in the cyclic AMP response element-binding protein (CREB)-binding protein gene.

More recently, many of the genes required for the storage and retrieval of long-term memory have been identified. The classes of function found in these genes have shown that long-term memory storage makes use of cellular mechanisms involving the localization of mRNAs to particular regions of the neuron, as well as those that regulate translation of mRNAs.

Figure 2 (Left) Male-specific neurons expressing the *fruitless* gene. (Center and right) Male vs. female difference in *fruitless* expressing neurons projecting from the olfactory lobes into the brain. Left panel modified from Yu, J.Y., Kanai, M.I., Demir, E., Jefferis, G.S.X.E. et al., Cellular organization of the neural circuit that drives *Drosophila* courtship behavior. Unlike the case of courtship and *fruitless*, the genes implicated in learning and memory are involved in many different cellular functions. Thus, mutations in these genes only exert specific effects on learning when either temporal or spatial restrictions are imposed on the gene's action.

From Genes to Circuits

Genetic Mosaics

Before the discovery of *fruitless*, experiments involving flies that are a mixture of male and female cells (called 'mosaics') were shown to behave like males if only small portions of their brain are genetically male, even if the rest of their cells and tissues are genetically female. This made it possible to 'map' the regions of the fly's central nervous system that govern male-specific courtship behavior.

One way of producing mosaic flies is to generate fertilized eggs that start out having two X chromosomes but lose one during the first few rounds of chromosome replication and division (mitosis). The result is a fly that has some of its cells male (1 X) and the rest female (2 Xs), producing a sex mosaic, or gynandromorph. By incorporating visible marker genes into the unstable X chromosome, mosaic individuals can be easily recognized by their patchy expression of the markers. More importantly, male portions of the brain can be seen directly in sectioned tissue at the end of the experiment, after the gynandromorph's behavior has been tested. Since no two mosaics have exactly the same clusters of male and female cells, each one becomes a separate experiment in the subdivision of the brain into one type of sexual development or the other. The uniqueness of each mosaic means that the experimenter has no second chance, and that the consistency of a particular pattern cannot be tested directly.

After examining many gynandromorphs, Jeffrey Hall concluded that the different steps in male courtship behavior were controlled by sex-specific development in certain parts of the central nervous system (Hall, 1977). In particular, the initiation of courtship (orienting toward the female, tapping her abdomen, following, and wing extension) required that only one side or the other of a relatively small region near the top of the fly's brain be male. This finding points to a region called the posterior dorsal supraesophageal ganglion as the site of a trigger mechanism that is present in males but not in females, which can receive sensory information and send out motor commands through other parts of the brain that will function properly whether they are male or female. In fact, most of the brain's circuitry is the same in both sexes.

Later steps in courtship, particularly those requiring precise motor coordination, require male tissue in additional parts of the nervous system. To sing a proper courtship song, for example, a gynandromorph must have male cells in the dorsal brain and parts of the midbrain, as well as in parts of the thoracic ganglion, the fly's version of a spinal cord.

Anatomical Mutants

Some of a fly's repertoire of visual response during flight can be observed in the laboratory where a tethered fruit fly will fly in a stationary position and attempt to orient itself according to the visual patterns it perceives (Figure 3). The fly's efforts at orientation to movement in its visual field constitute its optomotor response. Rapid motor responses to moving patterns in the visual field are widespread among animals with sophisticated visual systems, including humans.

Figure 3 Fly virtual reality. A fruit fly is suspended (from a wire glued to its back) in the middle of a flight arena, consisting of a cylinder of light-emitting diodes, on which images or patterns are displayed. The fly's wing beats are detected by means of an infrared laser that casts the wings' shadows onto a pair of sensors. The differential amplitude of the left versus the right wingbeat is then fed back through a computer to the image display, allowing the fly to control the position of the image and thus exhibit virtual tracking behavior. Reprinted from Greenspan, R.J., 2007. An introduction to nervous systems. Cold Spring Harbor, NY: Cold Spring Harbor Laboratory Press, p. 103, Figure 6.16. Copyright 2007, with permission from Cold Spring Harbor Laboratory Press.

Many mutants in the fruit fly have been isolated that are defective in the optomotor response, and as with phototaxis, most of these were subsequently found to affect components of the phototransduction machinery in the retina. Several, however, affected the behavior more centrally in the brain. One, in particular, was normal for vision at the level of the retina and displayed normal attraction to light, but showed a selective deficit in motion detection. It responded normally to a single stripe in motion, but failed to respond as normal flies would to a grate or a random array of stripes.

The mutant, known as *optomotor-blind*, was subsequently found to affect selectively the development of the visual system in the fly's brain (Heisenberg et al., 1978). It fails to produce a specific subset of large neurons in the most central optic lobes called horizontal-motion-sensitive (HS) and vertical-motion-sensitive (VS) giant fibers (Figure 4). In other words, the behavioral defect it causes is actually a developmental defect in the formation of a very specific part of the visual system. These are neurons known from electrophysiological recordings made in larger flies to be responsive to motion over a wide portion of the field of vision, and they receive widespread inputs from neurons in the more peripheral optic lobes. The behavioral phenotype of the mutant demonstrates directly the critical role of these cells in a restricted aspect of the optomotor response, a role that could only be inferred from their physiological properties.

Figure 4 The optic lobes (lobula plate) of *Drosophila* showing horizontal giant neurons (HS cells) in normal (left) and *optomotor-blind* mutant flies (right). Reprinted from Heisenberg, M., Wonneberger, R., Wolf, R., 1978. Optomotor-blind^{H31}—a *Drosophila* mutant of the lobula plate giant neurons. Journal of Comparative Physiology A 124, 287–296. Copyright 1978, with permission from Elsevier. lo: lobula; lp: lobula plate; m: medulla; psl: posterior slope of protocerebrum.

The *optomotor-blind* gene has been cloned, and its DNA sequence determined (Pflugfelder et al., 1992). It turns out to encode a protein that has homology to transcription factors, proteins that regulate gene expression, consistent with a role in development. The gene's pattern of expression, however, indicates that it is more widespread than simply the HS and VS giant neurons, encompassing much of the proximal optic lobes (Poeck et al., 1993). In other words, it is not a gene exclusively for HS and VS neurons. How, then, can the *optomotor-blind* mutation produce such a specific defect?

Further analysis revealed that this is a gene playing multiple roles in development, as reflected by its numerous regulatory regions (control sites in the gene for activating it at specific times and places). Mutations in these various regions produce different developmental defects, some much more severe than the simple loss of HS and VS cells. The original *optomotor-blind* mutation was caused by a disruption of one of the several regions of its DNA sequence – that responsible for HS and VS neuron development. Disruptions of adjacent control regions produce progressively more drastic disruptions of optic lobe development up to a full knockout of the gene, which is lethal and majorly disrupts development of the optic lobes.

Thus, even though this gene has a major role in the development of the entire optic lobes, because of the organization of

its regulatory sequences, it was capable of mutating to a behaviorally specific phenotype. This, in turn, revealed its function in the organization of behavior: the specification of HS and VS giant motion-detecting neurons. Thus, *optomotor-blind* represents a paradigmatic example of a specific behavioral effect of a mutation in a pleiotropic gene.

Localization and Genetic Targeting

A major advance over the gynandromorph technique, described above, came with the introduction into behavioral studies of an alternative approach to generating intersexual mosaics, making use of gene targeting. This technique, known as the *GAL4* method (Ferveur et al., 1995), permits concerted control of expression of a transgene in specific cells of the brain. (*GAL4* is a transcription factor from yeast that was adapted for the purpose of expressing transgenes in restricted tissues in *Drosophila*.) The experiments on courtship relied on the ability of the female form of the sex determination gene transformer (*tra*) to act dominantly and autonomously in males to drive cells into the female pathway of development. In contrast to the gynandromorph method, where each individual is unique in its pattern of mosaicism, the *GAL4* method produces an essentially unlimited supply of individuals with ostensibly identical patterns of mosaicism. It also produces a finer grained mosaicism than gynandromorphs, and with it the potential for higher resolution mapping.

The *GAL4* method demonstrated that feminization of restricted sets of neurons in the male fly brain was sufficient to induce those flies to court other males and females (Ferveur et al., 1995), as well as to identify sites in many other parts of the nervous system whose sex-specific development was necessary for courtship (Ferveur and Greenspan, 1998). Ultimately, most of these sites, but not all, turned out to be sites of *fruitless* gene expression. The technique is widely used in studies of behavioral circuitry.

The 'Connectome' and Behavioral Circuitry

In recent years, the idea of producing a complete map of neuronal connections in the brain, known as the 'connectome' (Sporns et al., 2005), has generated broad interest. The first such case of a complete map was produced for the simple ~300-neuron nervous system of the little nematode *Caenorhabditis elegans* (White et al., 1986), and the goal of completing a human connectome map has been variously estimated to take anywhere from 100 to 7000 years. Major efforts in this direction are currently under way (The open connectome project <http://openconnecto.me/>).

Fortunately, the connectome of the 130 000-neuron *Drosophila* brain is well on its way to completion in a more livable timeframe, due to the efforts of Ann-Shyn Chiang in Taiwan (Chiang et al., 2011). The first draft, of roughly 10% of the brain, was published in 2011, and the remainder is expected to be completed within a few years. A summary diagram of the major connectivity pattern among brain modules (known as 'local processing units') is shown in Figure 5. The work represents a major milestone as the first connectome map of a complex brain.

The existence of this map and its accompanying database with a record for each neuron (FlyCircuit <http://www.flycircuit.tw/>) has revolutionized the study of the circuits underlying behavior. Previous efforts, using gynandromorphs or gene targeting (see above), all involved anatomical verification of the pattern of gene expression in the brain, but this required either serial tissue sections or whole mount staining, both of which introduced substantial distortion. Consequently, prior to the current connectome map, the only individually

Figure 5 Major connectivity patterns of network connection in the *Drosophila* brain. identifiable cells in the fly brain were the handful that were large enough to have an easily recognizable morphology, such as the HS and VS neurons described above.

These problems have all been obviated now, due to improved techniques of sample preparation, clearing, and staining that introduce little or no distortion. The result is the tagging of individual neurons in a coordinate system that gives each neuron a recognizable identity from fly to fly. Starting from the technology of targeted gene expression (see above), this new resource not only makes possible the reliable mapping of functional tests of individual cells onto the reference map but also allows for the rapid and accurate prediction of other connected neurons and the reconstruction of a hypothetical and testable complete circuit. Its potential is already being realized.

A logical corollary to the full connectome map is to have a comprehensive brain activity map (Alivisatos et al., 2012), a project that is now being mounted. It is currently most feasible in small-brained organisms such as *C. elegans* and *Drosophila*, but the development of new technologies to allow access to larger brains is also under way.

From Component Parts to Networks

Networks of Genes

The search for genes has been a major concern of geneticists since variants first began to be mapped – the more the better for filling in spaces along chromosomes, regardless of phenotype. The quest has become more directed in the last several decades of developmental and behavioral genetics. The guiding assumption has been that mutants reveal the key players and they will explain the underlying mechanisms. There is no doubt that this approach has been successful in expanding and shaping our view of when, where, and how genes act.

Central to this worldview is the genetic pathway, originally modeled in conjunction with the enzymatic transformations of intermediary metabolism. The extension of the analogy beyond metabolism made its debut in phage morphogenesis where it represented the sequential assembly of a phage particle. In more contemporary studies, it has been further adapted to represent several kinds of processes including pattern formation and cell fate determination. It has even been stretched to apply to morphogenetic events and, in behavioral studies, to phases in memory consolidation.

The aspiration of this approach, based again on the phage morphogenesis work, is saturation mutagenesis for mutants 'specifically' affecting the phenotype in question. Sadly, this may have been applicable only to phage morphogenesis. We now know that the mutant search for early embryonic patterning missed many critical genes despite the fact that it met the criterion for saturation. This was due not only to the significant role of maternal genes in the formation of the embryonic axes but also, more importantly for this discussion, to the fact that many of the relevant loci did not (and presumably could not) mutate to a phenotype restricted enough to be picked out. Eventually, mutants in this more refractory class of genes were found by more indirect strategies (e.g., looking mutations based on interaction with known mutants, or based on tissue-specific patterns of expression).

The ensuing proliferation of identified genes has created a problem of interpretation, e.g., which genes are most important, and how do they all interconnect? Rather than running in linear paths, the increasing complexity of relationships among genes is better described as a distributed network. Some produce more damage than others when mutated, but this depends heavily on the context of other variants that are present, and so it is difficult to arrange them in a simple order of importance. The interactions that have defined various pathways are not wrong, just not exhaustive. They are part of a much larger picture.

Pleiotropy, as discussed above, has been the hallmark of behavioral mutant hunts all along, and the majority of behavioral mutants in the fly are the result of rare phenotypically specific alleles of genes that act more widely. Behavioral mutants are also extremely sensitive to variations in genetic background – the natural, genetic heterogeneity in laboratory stocks. The dependence of mutant phenotype on strain background has been well documented for learning mutants in the mouse (Gerlai, 1996), and the sensitivity of behavior to genetic background is a special case of the more general observation that mild genetic differences can produce large phenotypic effects on behavior (Greenspan, 2001).

These conclusions are also consistent with the findings on genetic changes that occur during multigenerational selection for behavioral phenotypes in the laboratory. There, a wide range of genes has been found to be capable of affecting phenotypes, and the variants are demonstrably mild and acting in combinations (Greenspan, 2009). These conclusions were made possible in large measure by the advent of genomic technologies. Knowing all the organisms' genes and their sequences has spawned technologies for comprehensively measuring the level of expression of every gene across the entire genome. Thus, by comparing genome-wide expression levels between strains differentially selected for a behavior, it became possible to infer a gene's involvement, and then to confirm it by direct testing of a mutant in that gene.

Such extreme sensitivity to subtle genetic variation, and the ubiquitous presence of the requisite variation, argues strongly against any sort of linear pathway model for the action of genes on behavior. It is unlikely that the variation needed to cause 'background effects' would be found so often if only a narrow set of dedicated genes was capable of interacting. This network of genes, in turn, must operate through the networks of cellular machinery and anatomy in the nervous system to influence behavior. The filtering through successive networks provides greater potential for interactivity and synergy.

Networks of Neurons

As judged by engineering standards, nervous systems are noisy. The signals in neurons are often not reproducible. Synaptic release can vary tremendously depending on the strength of stimuli to a cell and also depending on the cell's immediate past history. These effects are magnified many times over by the fact that neurons are highly interconnected in a dense network. In the nematode *C. elegans*, it has been possible to estimate the degree of connectedness. Theoretically, a sensory stimulus to four of the animal's sensory neurons would reach 6% of the animal's ~300 neurons directly in one step (i.e., through their

first synaptic connections), and 50% of the nervous system in two steps. That is in theory, but what about reality?

Using a technology that allows hundreds of neurons to be monitored for their electrical activity at the same time, rather than the two or three usually monitored in conventional electrophysiology, one of the simplest of behavioral circuits showed signs of being far less simple. The behavior is the reflexive gill withdrawal response of the sea snail *Aplysia*, which, in the hands of Nobel Laureate Eric Kandel, became a model system for understanding the cellular and molecular mechanisms of synaptic plasticity. *Aplysia* will close up the gills when touched. Kandel and colleagues showed that this is a simple sensory-motor reflex, in which the touching of the gill activates sensory neurons that synapse directly onto motor neurons that drive the muscles to close the gill (Pinsker et al., 1970).

When this response was monitored under the microscope, with a voltage-sensitive dye to indicate the electrical activity of the entire abdominal ganglion, it became possible to measure the reproducibility of the population of neurons active in the gill withdrawal response during repeated stimuli. There was significant variation in the number of cells, the identity of cells, and the strength of response of cells from one trial to the next (Wu et al., 1994). The number of cells responding is in the hundreds.

These *Aplysia* findings reinforce the theoretical prediction obtained in the nematode *C. elegans* that it is almost impossible to insulate the activities of neurons in one region from those in another. This means that some other strategy, aside from insulation, must be exerting itself. If the intrinsic variability in the nervous system cannot be reined in, then perhaps it is exploited.

In reality, nervous systems are potentially chaotic places. If one estimates the actual extent of connectivity in a system such as *Aplysia*'s gill withdrawal response, the potentially relevant circuitry is huge and tangled, with many hundreds or perhaps thousands of potential pathways intervening between sensory neurons and motor neurons. The response is distributed widely in the nervous system. Granting that not all such pathways are necessarily productive or consequential in their output, if they all exist and have some probability of occurring, and if many of them produce at least some degree of consequential output, then we are faced with the question of how the animal sorts out the useful from the wasteful.

General Conclusions

Our understanding of the genetic influences on behavior has grown substantially in the 50 years since the question began to be directly addressed. During that time, the perspective has evolved from that of single genes to many genes acting in networks, and from rough localization of function in the nervous system to a fine-grained coordinate system, onto which behavioral circuits are being mapped. As so often happens in science, the advances have brought with them new challenges, which are becoming focused on the question of how the large-scale, dynamic interactions of genes acting through nervous systems can be addressed. Arriving at a solution to this complex problem may then actually bring us close to a deep understanding of how genes affect behavior.

Genetic Admixture

Oscar Lao and Mannis van Oven, Erasmus MC – University Medical Center Rotterdam, Rotterdam, The Netherlands

Abstract

Genetic admixture plays a fundamental role in a species such as *Homo sapiens*, which has colonized the world on a relatively small evolutionary time scale, and has gone through complex migratory patterns in modern times. Several statistical methods exploiting different aspects of the genetic variation of admixed populations have been proposed. In this article, we describe the main consequences of genetic admixture for genetic variability, both in autosomal and paternally and maternally linked markers, introduce the state-of-the-art in methods for studying genetic admixture/genetic ancestry, and provide two key examples of genetic admixture in human populations: the human diaspora out of the African continent and the patterns of admixture in the American continent following Columbus' discovery.

Genetic admixture and genetic differentiation are two mutually dependent processes that have played a main role in shaping the neutral (not being under selective pressure) genetic variability of the human species. On the one hand, genetic admixture occurs when individuals from two or more different genetic backgrounds (or ancestries) migrate, mate, and produce descendants. On the other hand, a differentiated population genetic background is due to prolonged genetic isolation among populations, as a result of the absence of migration and genetic admixture between them. Since new populations appear by splitting from previous ones, genetic ancestry (and hence genetic admixture) has also a temporal dimension: one can define and infer genetic ancestry at different time scales, taking into account that all individuals from a species ultimately share a common genetic origin.

Detecting the genetic fingerprint of admixture and isolation processes in human populations is of main interest for human population geneticists, and the development of new methods for detecting such events has been constant in the literature (Verdu and Rosenberg, 2011), since 1931 (Bernstein, 1931). These methods, in addition to the availability of hundreds of thousands of single nucleotide polymorphisms (SNPs) genotyped in thousands of worldwide individuals (Novembre and Ramachandran, 2011), are providing a new and very detailed picture of the genetic landscape of human populations, as well as the underlying historical processes that shaped them (Gutenkunst et al., 2009).

The two basic models mostly used in human population genetics to describe genetic admixture events are depicted in Figure 1 (adapted from Long, 1991). Both models share the *sine qua non* condition of the existence of genetic differentiation between two parental populations (although by definition these parental populations ultimately share a common origin) that is acquired by means of long-term genetic isolation after the split from the ancestral population. Moreover, the number of breeding chromosomes (understanding that each diploid individual carries two chromosomes) in each generation and population (also known as effective population size or N_e, Hartl and Clark, 1997) is assumed to remain constant through time. In the *continuous-gene-flow* (*CGF*) model, *m* chromosomes from one population migrate to the other population since *t_admixture* generations ago, and replace the same proportion of chromosomes in the mating process. In the *hybrid-isolation* (*HI*) model, two parental populations create a new hybrid population in a single pulse event of admixture *t_admixture* generations ago, which then starts evolving independently from the parental populations. More complex models can be constructed from these basic models by considering different effective population sizes (Bertorelle and Excoffier, 1998), allowing successive migrations from the parental populations to the hybrid one (Verdu and Rosenberg, 2011), or considering more than two parental populations (Dupanloup and Bertorelle, 2001), among others.

A basic question of interest for population geneticists is the timing of admixture (*t_admixture*), the proportions of migrants (*m*) that were exchanged between populations and the number of parental ancestral populations that contributed to the current genetic variability. Furthermore, it can be important to determine the ancestry proportions in the genome of each individual or to detect fragments of genomic ancestry. Depending on the question of interest, the statistical methods focus on exploiting the genetic variability of the parental and admixed populations, the amount of individual ancestry or the genomic ancestry at a regional level. Depending on whether we are interested in studying sex-mating biases between the parental populations, or average migration patterns, current statistical methods use uniparentally inherited markers or autosomal markers, respectively, or a combination of both. We next describe some of these properties and the main statistical tools so far developed that take advantage of them.

Autosomal Genetic Admixture at the Population Level

Linkage Disequilibrium in the genome of the admixed population. Linkage disequilibrium (LD) refers to the nonrandom association between the allelic frequencies of two markers in a population (Slatkin, 2008 for more details). Recently admixed populations tend to show in their genome an overall excess in the levels of LD (Pfaff et al., 2001). The levels of LD decay exponentially since the time of admixture (Figure 2(a)) and therefore can be used to make inferences about this parameter (Patterson et al., 2012; Pfaff et al., 2001).

Figure 1 Basic admixture models commonly used in population genetics. Each circle represents a population. Both models consider one initial ancestral population (gray color) that splits into two new populations t_{split} generations ago. Each of the new populations evolves without exchanging migrants for a period of time, during which genetic differentiation between them can take place. (a) *HI* model. At *t_admixture* there is a single event of admixture, and a new hybrid population is created from *m* fraction of chromosome migrants from the blue population and $1-m$ fraction of migrants from the red population. After this event, each population continues to evolve independently; (b) *CGF* model. The blue population contributes *m* chromosome migrants to the red population, replacing the same number of chromosomes from this population. Adapted from Long, J.C., 1991. The genetic structure of admixed populations. Genetics 127 (2), 417–428.

Genetic similarity of the admixed population with the parental ones. Initially, admixed populations have allele frequencies that are linear combinations of the allele frequencies in their parental populations. With time after the admixture event, the allelic frequencies in the parental and admixed populations randomly fluctuate due to genetic drift (the change in allele frequency in a population due to random or chance events rather than natural selection), and genetic differentiation between them occurs. Nevertheless, the expectation of linearity still holds if a large number of unlinked loci are considered. Therefore, the degree of genetic similarity between the admixed and the parental populations can be used to make estimations of the migration rate in the admixed population (Long, 1991; Patterson et al., 2012; Pickrell and Pritchard, 2012) or to statistically compare particular population phylogenies (Patterson et al., 2012; Pickrell and Pritchard, 2012). A traditional statistic based on allelic frequencies summarizing the amount of genetic differentiation among populations is F_{st} (Holsinger and Weir, 2009). This statistic is proportional to the time of admixture and population split, although it is highly dependent on the demographic assumptions of the model (Verdu and Rosenberg, 2011), and does not consider other aspects of the genetic variants, such as the number of evolutionary steps separating different alleles, which can provide additional information about the admixture process. The *my* statistic (Bertorelle and Excoffier, 1998) and its extension to any number of parental populations (Dupanloup and Bertorelle, 2001), or maximum likelihood approaches such as the one implemented in the program LEADMIX (Wang, 2003) or MEADMIX (Wang, 2006) use the coalescence framework to estimate the different admixture parameters by taking into account this fact.

Autosomal Genetic Admixture at the Individual Level

Population methods for quantifying admixture require prior knowledge and a definition of what a population is, which in some cases can be particularly difficult (if not impossible) to obtain (Pritchard et al., 2000). Therefore, several methods for estimating individual ancestry proportions without taking into account any population sampling information have been proposed. Depending on the applied statistical strategy, these methods have been divided into *global ancestry-based methods* and *local ancestry-based methods* (Alexander et al., 2009).

Global ancestry-based methods are applied to estimate the number of the ancestral populations that shaped the observed current genetic diversity, infer their ancestral genomic composition, and quantify their contribution in the genome of each current individual (Figure 3). Depending on whether the statistical method takes into account the expected allelic frequencies of the ancestral populations or not, global ancestry-based algorithms have been subdivided into *model-based ancestry estimation* (Alexander et al., 2009) and *algorithmic ancestry estimation* (Alexander et al., 2009) (Figure 3). In the first case, the main aim is to infer the genetic variation of the ancestral populations, and their contribution to the genome of each current individual. Popular algorithms implementing such approach include STRUCTURE (Pritchard et al., 2000), FRAPPE (Tang et al., 2005), and ADMIXTURE (Alexander

Figure 2 Effect of genetic ancestry at a local level. (a) Chromosomes of parental population 1 (with blue ancestry) and parental population 2 (red ancestry) admix into a new hybrid population. As time since admixture passes, chromosomes from the different ancestries collide in the same individual and recombine, creating a mosaic of ancestries (t_n). Adapted from Pugach, I., et al., 2011. Dating the age of admixture via wavelet transform analysis of genome-wide data. Genome Biology 12 (2), R19; (b) decay of the patterns of linkage disequilibrium (LD) in a simulated admixed population with the time since the admixture event (in number of generations). LD was estimated by means of r^2 between markers with a MAF of 0.5 and at 1 Mb distance. The effective population size (N_e) of each parental and admixed population was 2000 diploid individuals (i.e., 4000 chromosomes). Random monogamous mating was assumed. The admixed population was created for each simulation by admixing 1000 individuals from parental population 1 and the same number of individuals from parental population 2. Both parental populations merged into a single one 5000 generations ago. Eighty diploid autosomal genomes were sampled in each simulation; each genome comprised 22 pairs of autosomal chromosomes, each one proportional in length to the human chromosomes (Gravel, 2012). The mutation rate was set to 2.5×10^{-8} and the recombination rate to 1.8×10^{-8}. The demographic and genomic parameters used to generate the simulations were chosen to be illustrative of the different genomic processes, and are not intended to be representatives of human population history.

et al., 2009), among others. In the second case, the output is a set of coordinates for each individual in a new reduced Euclidean space (Jombart et al., 2009; Figure 3), in which each dimension can be interpreted as a locus with an infinite number of alleles (Menozzi et al., 1978), and the proximity between two individuals in this space as genetic similarity between them (Patterson et al., 2006). Principal component analysis (PCA; Patterson et al., 2006) and classical multidimensional scaling (classical MDS; Cox and Cox, 2001) are typical examples of algorithmic ancestry estimation, mainly applied to SNP data.

Besides inferring individual ancestry proportions and the number of ancestral populations, these methods can be used to get estimations of the demographic parameters associated to the admixture events. For example, ancestry proportions in older admixture events will tend to be homogeneously distributed among the individuals of the admixed population; in contrast, relatively recent admixtures are going to produce individuals carrying large proportions of the ancestries, thus increasing the ancestry variance among them (Figure 4). Therefore, the variance in the proportions of genomic ancestry between individuals of the admixed population can be used to make inferences about the magnitude, timing, and frequency of the admixture event (Verdu and Rosenberg, 2011). Similarly, it has been shown that the coordinates in the first dimension estimated by PCA tend to be proportional to the amount of genomic ancestries in the admixed individuals (McVean, 2009) (Figure 4). However, since global ancestry-based methods do not explicitly fit historical models, or unrealistically assume that all the ancestral populations have radiated from a single ancestral group (Figure 3), it has been suggested that the biological interpretation of their outcome can be cumbersome (Patterson et al., 2012). Nevertheless, despite these limitations, the methods for inferring genomic ancestry at individual levels are fundamental tools in interpreting the current genetic variability in human population genetics (see below).

Local ancestry methods. As already stated before, after an event of admixture between individuals of different genetic ancestry, recombination tends to break the chromosomes into blocks of genomic ancestry (Figure 2(a)); at a population level this is translated into patterns of LD; at an individual level, this process means that the genome of one individual can be considered as a mosaic of different ancestries (Figure 2(a)). *Local ancestry methods* (Alexander et al., 2009) try to estimate the ancestry of each locus in a given individual. If the genomic marker density is large enough, such as in the case of SNP microarrays (Novembre and Ramachandran, 2011), local ancestry methods will define blocks of genomic ancestry, also referred to as 'ancestry painting.' So far, several algorithms based on different statistical approaches and assumptions have been proposed for identifying such ancestry tracks (Pugach et al., 2011, for a list of algorithms). Most of these require previous knowledge of the genetic variation of the parental populations or, if such information is not available, of proxy parental populations (i.e., HapMix and StepPCO algorithms (Price et al., 2009; Pugach et al., 2011); Figure 3). Similarly to *global ancestry-based methods*, the output of local ancestry methods can provide insights into the values of the demographic processes at a population level because large ancestry fragments in the admixed population are indicative of recent and ongoing migration processes, whereas small ancestry fragments are suggestive of older migratory events (Gravel, 2012; Figure 3).

Sex-Biased Admixture

In contrast to the autosomes, there are two genetic loci that are haploid and do not undergo recombination: the maternally inherited mitochondrial (mt) genome (carried by males and females), and the paternally inherited Y chromosome (that is to say, the nonrecombining portion of it, referred to as NRY) (carried by males only). Despite differences in their size, genetic organization, mutation rate, and cellular localization (Jobling

Figure 3 Schematic representation of the *Global ancestry-based methods* to detect individual genetic ancestry. Starting from a matrix of genotypes (coded 0, 1, and 2 for homozygotes for allele A, heterozygotes and homozygotes for allele B, respectively) of *m* individuals by *n* biallelic markers, the algorithms are classified into two main types. *Algorithmic ancestry estimation* methods apply algebraic transformations to obtain a new representation of the genomic coordinates of each individual (each purple dot) in a reduced space, so the genetic relationships between the individuals can be better identified. *Model-based ancestry estimation* methods aim for estimating the number of ancestral populations (in the current example: four) that shaped the genetic variation of the matrix and the ancestry proportions (α_i) for each individual, which can then be visualized by means of a bar. The underlying demographic history of the ancestral populations is shaded, since it is not modeled.

and Tyler-Smith, 2003; Pakendorf and Stoneking, 2005), mtDNA and NRY have in common their unique uniparental inheritance pattern. The process of hundreds of thousands of years of human evolution has yielded DNA variation in both NRY and mtDNA as a result of the accumulation of spontaneous mutations along radiating lineages. All haplotypes existing today are ultimately related genealogically and their relationships can be represented by detailed phylogenetic trees, which have been constructed for both NRY (Karafet et al., 2008; International Society of Genetic Genealogy, (http://www.isogg.org/tree/)) and mtDNA (Torroni et al., 2006; van Oven and Kayser, 2009). Shared (sets of) mutations between two haplotypes are indicative of a shared uniparental ancestor at some point of time in history. Such mutations can thus be used as evolutionary markers that define clusters of related haploid genetic lineages, or haplotypes (haplogroups). Each haplogroup has its own specific evolutionary history and associated geographic distribution, shaped by different demographic processes (Cavalli-Sforza and Feldman, 2003; Underhill and Kivisild, 2007). As a result of their mode of inheritance, NRY and mtDNA reflect very specific aspects of a person's ancestry, namely that of the father's father's father, etc. and that of the mother's mother's mother, etc., respectively (Figure 5; Shriver and Kittles, 2004). It is important to note that uniparental ancestry does not necessarily need to agree with an individual's overall ancestry (King et al., 2007). In fact, uniparental markers can provide additional insights into the evolutionary history of human populations, such as the mating process that gave rise to admixed populations, which cannot be inferred by other means.

The Complexity of Human Demographic History

The demographic history of *Homo sapiens* is far more complex than the models depicted in Figure 1. Although from an evolutionary point of view, anatomically modern humans can be considered relative newcomers, the species has managed to colonize the whole world after dispersing out from the African continent (Cavalli-Sforza et al., 1994; Liu et al., 2006). During this first main migration, anatomically modern humans

Figure 4 Three methods estimating individual ancestry on simulated data using the *HI* model at three different times of admixture (5 generations ago, 10 generations ago, and 1000 generations ago). The demographic parameters used to generate each simulated dataset is the same as in **Figure 2**, with the exception that in this case, 70% of migrants come from parental population 1 and the remaining 30% from parental population 2. Each dataset comprised 80 sampled individuals from each population. First row: classical MDS on identical-by-state (IBS) distance matrix between pairs of individuals. Each dot represents one individual. Red dots parental population 1, blue dots represent parental population 2, and orange dots represent the admixed population. One of the admixed individuals is marked as black since it is also used in StepPCO analyses. The coordinates of the first dimension have been rescaled so the mean value for parental population 2 is 0 and for parental population it is 1. As can be observed, the admixed individuals tend to be distributed around 0.7 in the first coordinate for times of admixture <100 generations, mimicking the initial proportion of migrants from the parental population 1. Second row: ADMIXTURE analyses on the same data assuming two ancestral populations. Each individual is represented by a bar (**Figure 2**), and individuals from the same population situated contiguous into the same block. The red component, indicating parental 1 ancestry, shows a mean of 0.7 in the admixed population for times <100 generations, and departs from this value as the amount of genetic drift increases (in the example, ∼0.8 at 1000 generations of split). Note also that the variation of the red ancestral component between admixed individuals decreases as the time since admixture increases. Third row: StepPCO analyses on one admixed individual (black dot in the MDS plots, the first admixed individual in the ADMIXTURE analyses) to detect tracks of ancestry. The plot shows the simulated genome of the individual in the *X*-axis and the ancestry values estimated by means of principal component analysis in the *Y*-axis for parental population 1 (red line), parental population 2 (blue line), and the individual of interest (black line). At a time of admixture of five generations ago, the black line tends to be on the red line (indicating long tracks of parental 1 ancestry). As the time since the admixture event increases, the black line starts alternating more frequently between the two parental populations, indicating short genomic fragments of ancestry.

encountered other *Homo* species (such as *Homo neanderthalensis* in Europe) and had the possibility to interbreed with them (Abi-Rached et al., 2011; Green et al., 2010). Following this first main migratory wave, other ancient migrations, mainly associated to technological developments such as farming, took place at a more regional level (Diamond and Bellwood, 2003). Whether these technological migrations were accompanied by demographic movements, admixture or replacement with the autochthonous populations is sometimes difficult to decipher (e.g., see the discussion in Pinhasi et al., 2012 in the case of the European continent). Moreover, the fact that subsequent migrations may have followed geographic patterns similar to the previous ones adds another layer of complexity for disentangling the effect of each historical process in the genetic variation of the genome (Jobling et al., 2004). Furthermore, humans tend to mate predominantly to individuals from the same (or close by) geographic area, which creates an effect of isolation by distance in the amount of genetic differentiation (Ramachandran et al., 2005). In addition, other factors, including language and cultural differences, can also influence the amount of genetic exchange among unrelated individuals (Oota et al., 2001).

One of the first main consequences of the demographic history of humans is a considerable lack of genetic differentiation within the species compared to that observed within other nonhuman primate species including our closest living relative the chimpanzee (Foley, 1998). A practical result of this

Figure 5 Inheritance patterns of NRY (Y) and mtDNA (mt). The eight different colors represent eight different genetic ancestries. Considering the four generations depicted, the individual at the bottom (a male) inherited his NRY type ('red') exclusively from his patrilineal great-grandfather (upper left) and his mtDNA type ('blue') exclusively from his matrilineal great-grandmother (upper right), whereas his autosomes (not shown) consist of fractions derived from all of his eight great-grandparents.

observation is that detecting population substructure and patterns of admixture in humans requires the use of powerful statistical tools such as these introduced in previous sections. A second consequence of the evolutionary history of *H. sapiens* is that its genetic variation follows clinal patterns in the space rather than sharp discontinuities (Handley et al., 2007), and genetic differences between individuals tend to be strongly correlated with sampling geographic distances (Wang et al., 2012; Yang et al., 2012). Admixture estimations tend to depend on which algorithm is applied (Barbujani and Belle, 2006), the type (i.e., short-tandem-repeat polymorphisms or SNPs) and number of markers (Wang et al., 2012), the considered populations (Xing et al., 2010) and the sample size of the populations (McVean, 2009). Taken altogether, it has been suggested that human genetic variation challenges the concept of 'population' in humans (Barbujani and Colonna, 2010).

1. Detecting ancient human migrations and admixture

Despite these caveats, the statistical methods previously introduced are substantially improving our knowledge about the past of the species. Figure 6 shows the application of three methods for studying the genetic ancestry and admixture in 53 worldwide populations from the Human Genome Diversity Project–Centre d'Étude du Polymorphisme Humain (HGDP-CEPH) panel commonly used in human population genetics (Cavalli-Sforza, 2005); see map in Figure 6(a), using the genotypic information of ~650 000 SNPs (Li et al., 2008).

The first analysis (Figure 6(a)) uses F_{st} distances between pairs of populations to infer a phylogenetic tree by means of the neighbor-joining algorithm (Saitou and Nei, 1987). The topology of the tree obtained is similar to the one depicted in Figure 1 of Li et al. (Li et al., 2008), even if in that case the authors used a different approach, and to the one proposed by (Pickrell and Pritchard, 2012), which also incorporates admixture events and used a subset of ascertained markers. The tree shows non-African populations as splitting from African sub-Saharan populations, thus supporting the out-of-Africa model (Excoffier, 2002). Outside the African continent, the tree suggests a series of successive population splits, which mostly matches continental subdivisions and, within each continent, with the geographic distances between populations (Ramachandran et al., 2005; Rosenberg et al., 2005). The second analysis (Figure 6(b)) is a classical MDS analysis based on IBS distances between pairs of individuals. The plot shows the genetic similarities between the HGDP-CEPH individuals in the first two dimensions. Supporting the previous analysis, African sub-Saharan individuals tend to be differentiated from the other individuals in both dimensions. Outside the African continent, individuals tend to cluster according to their continent of origin and are distributed in a West to East pattern. Such geographic dependence with the genomic landscape can be highlighted if both dimensions are counter clock rotated (Wang et al., 2010, 2012). The MDS also highlights the presence of some individuals showing different ancestries than the other individuals from the same population. This is, for example, the case with the Mozabite population (red dots), which on average are genetically similar to European and Middle Eastern populations. However, some Mozabite individuals show strong genetic similarities with African sub-Saharan populations, thus indicating recent genetic admixture (Henn et al., 2012). The third analysis, an ADMIXTURE analysis (Figure 6(c)), was performed to estimate the ancestry proportions in each individual assuming seven ancestral populations. This number was chosen to compare results with the ones obtained with FRAPPE algorithm, initially applied on the same data (Li et al., 2008). ADMIXTURE analysis showed that the ancestral components tend to be associated to the continent of origin of current human populations, yet showing some degree of admixture within each population and individual. Compared to FRAPPE results, the ADMIXTURE analysis detects additional population substructure within the African sub-Saharan populations,

Figure 6 Application of three different methods to the study of the genetic variation present in ∼650 000 SNPs (Li et al., 2008) using the HGDP-CEPH panel, which comprises 53 worldwide human populations. (a) Neighbor-joining tree based on an F_{st} distance matrix between pairs of populations, using the San as out-group; (b) Classical MDS on an IBS distance matrix between pairs of individuals; (c) ADMIXTURE analysis using $K = 7$.

but fails to detect population substructure between Middle Eastern and European populations. Besides these discrepancies, both FRAPPE and ADMIXTURE results tend to correlate, in that they detect similar proportions of African sub-Saharan ancestry in Mozabite individuals (and thus supporting the previous observation based on MDS results), and in detecting East Asian ancestry in the Melanesian individuals, among others.

2. Detecting recent human admixture: the case of the post-Columbian admixture in the Americas

One prime example of large-scale recent admixture between humans originating from different continents can be observed in the Americas. The American continent was first colonized by anatomically modern humans from Siberia via the Bering route (O'Rourke and Raff, 2010). Native American populations tend to show genetic patterns in agreement with this route of migration, with a constant decay of genetic diversity from North to South of the American continent (Reich et al., 2012; Wang et al., 2007). However, following the European discovery of the Americas by Christopher Columbus in the year 1492, a complex admixture process, involving resident American natives, invading European colonizers, and forcibly moved African slaves, began. As a result, the genetic make-up of many contemporary Americans is a mosaic of those three ancestral populations, in some cases supplemented with other ancestry components (e.g., West Asian, South Asian, and East Asian) that reached the Americas during subsequent centuries through migration (Eltis, 2002). The relative contribution of each of the continental founder populations differs drastically depending on the subregion or the self-declared ethnic group within the Americas (Galanter et al., 2012; Figure 7), to the extent that in most of the cases these group assignations can be considered cultural constructs with little genetic support (Kittles and Weiss, 2003). Furthermore, additional sub-continental population substructure can also be detected within self-identified groups, such as within US European Americans (Campbell et al., 2005), US African Americans (Tishkoff et al., 2009; Zakharia et al., 2009), and US Hispanic Americans (Wang et al., 2008).

Interestingly, by analyzing the ancestry of NRY and mtDNA it has been shown that the admixture process was quite often sex-biased. For example, mestizo populations of Latin America usually carry predominantly Amerindian mtDNA types, but predominantly European NRY types (Bryc et al., 2010) indicating that the historical admixture involved mostly Amerindian women and mostly European men. A similar mating trend is also observed in the US African American

Figure 7 European, African, and native American components estimated in 18 Latin American populations, using ancestral informative markers (AIMs). Map adapted from Galanter, J.M., et al., 2012. Development of a panel of genome-wide ancestry informative markers to study admixture throughout the Americas. PLoS Genetics 8 (3), e1002554 using the ancestry frequency Table 4 of that article.

population (Figure 8; Lao et al., 2010; Lind et al., 2007; Stefflova et al., 2009), where the genetic ancestry of the mtDNA can be traced back almost entirely to the African sub-Saharan continent, whereas approximately 30% of the NRY ancestry is of European origin. In contrast, self-identified US European Americans show little evidence in their genomes of non-European ancestry (Figure 8; Lao et al., 2010; Lind et al., 2007; Stefflova et al., 2009).

This raises the question of why descendants from African and European ancestry couples tend to be perceived as US African Americans, rather than assigned at random to one of the two parental groups. One possible explanation that has been suggested (Lao et al., 2010) is that self-identification in admixed individuals tends to be biased toward visible traits with a biological basis such as skin pigmentation combined with cultural–sociological aspects (Bamshad and Guthery, 2007).

Concluding Remarks

Given the particular evolutionary history of humankind, mostly involving recent migrations, genetic admixture has played a major role on shaping the genetic variability of our genome. However, identifying such genomic fingerprints is complex and requires studying different aspects of the genomic variation within populations, individuals, and genomes. The development of new powerful statistical tools for detecting genetic admixture aids us to unravel details from our demographic past that could not be inferred otherwise. These statistical developments, together with the current technological advances in genome sequencing (Abecasis et al., 2012), hold the promise of an unprecedented level of resolution for detecting hidden genealogical relationships (Lawson et al., 2012) and genetic admixture processes in the near future.

Figure 8 Estimation of genetic ancestry in unrelated African American individuals (ASW) from the HapMap III project (Altshuler et al., 2010) using Yoruban (YRI) and European American (CEU) individuals as proxy parental populations. (a) First two dimensions of a classical MDS on an IBS distance matrix computed with autosomal data (∼1.2 million SNPs). Each dot represents one individual. The first dimension has been rescaled so the mean value is 0 for CEU and 1 for YRI individuals. ASW individuals are distributed in the first dimension around 0.78 (ranging from 0.59 to 0.96); (b) ADMIXTURE analysis on the same data. Each bar represents one individual. In agreement with the MDS result, the African sub-Saharan ancestral component (red color) represents on average 78% (ranging from 59% to 96%) of the genome of ASW individuals; (c) Continental African sub-Saharan and European ancestry estimated on NRY variation, mtDNA, and autosomal data (ADMIXTURE result) in ASW individuals.

Genetic Ancestry Testing

Jessica Bardill and Nanibaa' A Garrison, Stanford Center for Biomedical Ethics, Stanford, CA, USA

Abstract

From the large public interest in genealogy to academic research in human genetic diversity, genetic ancestry testing is a developing area that requires attention to interpretation of data and the ethical involvement of people and human populations. This article reviews the important definitions in genetic ancestry testing, ethical considerations in the uses of genetic ancestry testing, large-scale projects (including commercial ventures) that use the technology, and finally the limitations that have to be considered in uses of the tests.

Introduction

Ancestry can refer to different parts of an individual's lineage, such as close biological relatives or more distant ancestors. Primarily, it includes *where* someone's ancestors came from but also importantly *when* that person's ancestors lived in that place. Gathering information such as family stories and birth records provides information about both where and when one's ancestors are from and are important for reconstructing personal ancestral histories. To go further back into one's personal ancestral history, many people have turned to genetics to uncover their past. Due to genetic recombination, a process that shuffles what genes come from a person's mother and what genes come from the father, taking place at every generation, different gene segments are passed down from one generation to the next. Each gene segment, or small part of the parental genome, has its own ancestral history. Based on information about the connections between populations and particular gene segments, scientists can use that information to analyze an individual's genome to trace their lineage to different ancestral histories and populations. For example, one gene segment might be traced to Africa while another gene segment might be traced to Europe. When looking for individual lineage or family history in genealogical information searches, individuals may turn to genetic ancestry testing (Royal et al., 2010). Genetic ancestry tests use a person's DNA to gain information about where their ancestors were from many generations ago.

Genetic ancestry testing has grown in popularity among the general public as a tool to allow people to learn more about their own personal lineage, also referred to as their ancestral genetic history. Interest in genetic ancestry has also been stimulated by marketing from direct-to-consumer (DTC) testing companies. It remains a popular topic among researchers in areas as diverse as human migration and disease susceptibility. While popularity has driven technological and statistical innovations in these tests, genetic ancestry testing requires ongoing evaluation of its risks and limitations. This evaluation includes consultation or even partnerships between research and consumer communities, which involves making the tests' basic science, including their limitations, accessible to all involved in research and consumer testing. Scholars have noted the ethical implications of the concept of genetic ancestry and its testing (Lee, 2012) and remarked on the lack of standards and uniformity across DTC companies (Lee et al., 2009). However, other scholars are dedicated to identify more genetic markers to make these tests more precise and useful to individuals as well as for further research questions (Nassir et al., 2009). Recent research on consumer attitudes and knowledge about genetic ancestry testing (Wagner et al., 2012) has noted a gap between overall understanding that is related to different sets of information presented through commercial venues. An overview of genetic ancestry testing presented to the United States Congress also demonstrates the interrelations between these attitudes, lack of standards, and it argues for the place of policy and legislation or other protections for individuals and groups (Sarata, 2008). This policy briefing demonstrates how different motivations of consumers, variable knowledge of genetic science and statistics, as well as little to no regulation or standardization within the industry, create further confusion in the populace, as well as in between the companies.

This article reviews the important definitions in genetic ancestry testing, ethical considerations in the uses of the testing, large-scale projects (including DTC companies) that use the technology, and finally limitations of the tests themselves. This article attempts a comprehensive examination of the most widely used tests and their implications, but does not attempt a truly exhaustive examination, instead pointing to additional areas for exploration.

Concepts and Definitions

Ancestry

Ancestry as used here refers to a person's genetic lineage, which includes close familial relatives as well as more remote ancestors from hundreds or thousands of years previously. The difference in time, or *when* these relations occurred, combined with particular geographical locations, or *where* those ancestors came from, provides information about different parts of a person's ancestry.

Deep Ancestry versus Near Ancestry

When examining the uses of genetic ancestry testing for academics and the public, it is important to think about two types of ancestry: deep ancestry and near ancestry. Deep ancestry refers to many thousand years ago in a person's lineage, outside of the scope of most genealogical records. On

the other hand, near ancestry refers to close relatives, such as parents, grandparents, and other immediate relatives who are living or lived around the same time as the person who is interested in investigating his or her own ancestry. The scientific and statistical methods that are used to understand a person's ancestry vary for deep versus near ancestry. These methods produce an estimate of how much of one's genetic background matches up with database information to determine whether there is a match to one ancestry group or another. These results are referred to as ancestry estimates. Scientists use statistical analyses to make inferences about a person's ancestry, where that ancestor lived, and how long ago that ancestor lived.

Biogeographical Ancestry

Biogeographical ancestry refers to the connection drawn between a genetic sequence and a geographical location. These connections are also known as associations. This geographical location is further connected to a group of presumed ancestors by matching up information from the genetic variation of modern populations living in these geographical areas to a particular genetic sequence (Royal et al., 2010; Nassir et al., 2009). A researcher uses statistical estimates of multiple DNA markers to infer deep ancestry. DNA markers have been identified as being unique to certain modern populations living in particular geographical locations, also known as reference populations, and are used to estimate how similar or different a DNA sample is to that reference population. This genetic information is conveyed as 'ancestry proportions' that are correlated with human reference populations in specific geographical locations in order to infer how much of one's genome is similar to the reference population. A scientist might provide ancestry estimates about a person's genome that can be divided into multiple proportions of ancestry that add up to 100%. For example, a person's genome may comprise of three estimated proportions of ancestry: 50% European, 40% African, and 10% Native American. These proportions, or probable percentages of the genome distributed by geography, are determined through the use of multiple ancestry informative markers (AIMs) and a set of ancestry estimates. By itself, it may not provide sufficient genealogical information but can add to known genealogical information.

The related concept of 'continental ancestry' similarly focuses on geographical origins represented by five major parental populations (which are typically the continental areas of Africa, Europe, Asia, Native America, and Oceania) to which a person's sample is then correlated. This correlation refers to ancestry from hundreds or thousands of years previously.

Types of Genetic Ancestry Tests

Genetic ancestry testing relies on multiple kinds of genetic tests, including mitochondrial, Y-chromosome, and autosomal tests. Depending on the genetic test, an ancestry test can provide specific information about single branches of individual family trees, or they can additionally provide broad information about multiple branches of those family trees.

Much of the time, a kind of DNA marker known as a single nucleotide polymorphism (SNP) is used as a piece of information in a genetic ancestry test. When a given sample is genotyped, or processed to determine the genetic makeup of the sample, it can then be compared against reference sets of samples that have also been genotyped for similarities and differences. SNPs are allelic variations that occur on the level of one nucleotide change (A, T, G, or C) that differs from one person to another; for example, the difference between AATC[**C**]GT and AATC[**G**]GT. As a group, SNPs represent 90% of human genetic variation. SNPs have proven more abundant in certain populations than others, so a given sample is compared against a database of SNPs across populations. In genetic ancestry testing using SNPs, the number of SNPs between that sample and populations in the database can help determine a probability for origin. In order to be considered a useful marker, the SNP frequency has to be present in at least 1% of the populations under consideration, otherwise it would be too rare to be accurate. These results have not yet proven conclusive to the satisfaction of many in the field, including the presentation of results to the consumer without adequate background, interpretation, and analysis.

Mitochondrial DNA Testing

Mitochondria are organelles in eukaryotic cells that engage in energy production and cellular respiration. They also have their own genomes, known as mitochondrial DNA (mtDNA), that are distinct from the nuclear genome of a given cell. Mitochondrial genomes are found in all humans, but are inherited strictly maternally (from mother to offspring), and the mitochondrial genome does not undergo a process of recombination in the process of reproduction. Mitochondrial genetic variations are passed down through generations, from mother to child, and can therefore be tracked back through those ancestral generations along the maternal lineage. Mitochondrial lineages are defined by these genetic variations that are individually designated with letters and subgroup identifications (numbers and letters), also known as 'haplogroups.' The haplogroups are linked together in a large family tree that shows how different human groups are related to each other based on mtDNA information. The origins of different haplogroups are associated with given geographical regions. For example, the mtDNA haplogroup L is understood to have originated in Africa, and many African women are of this mitochondrial lineage.

Y-Chromosome Testing

Unlike the mitochondria that all humans inherit from their biological mother, only males have and share Y-chromosomes. The Y-chromosome is the sex-linked male chromosome that is passed from biological father to son, allowing a male individual to trace their paternal genetic lineage. The nonrecombining portions of Y-chromosomal DNA (also known as the NRY) are analyzed using genetic techniques, also known as genotyping, to identify SNPs and short tandem repeats (STRs), another type of allelic variation in the genetic sequence. While females do not have Y-chromosomes and therefore cannot use Y-chromosomal information to gain information about their genetic paternal lineages, they can learn more about that part of their genealogy if a close male relative in their father's line elects to have the testing and share information.

Ancestry Informative Markers

Ancestry informative markers (AIMs) are a collection of genetic markers that assist in providing estimations of genetic ancestry.

Markers were selected as AIMs if they had large allelic frequency differences (such as 30–50%) between populations. In most cases, SNPs are used as AIMs. There now exist multiple databases of AIMs that can be used in testing a sample or large set of samples to determine their probable origins. AIMs demonstrate shared genetic variation which typically correlates to shared ancestry, but which may also be the result of shared environmental changes and selective pressures without shared ancestry. Generally, around 50 AIMs could provide some information about the continental ancestry of a person, but more AIMs (such as several thousand) involved in the genotyping allow more certainty. A genetic ancestry test based on AIMs can provide consumers with an idea of their ancestry as best determined by comparing it against the company's database.

Uses and Ethical Considerations

Genetic ancestry tests have a particular utility for understanding genetic connections between persons. Their use to discern deep ancestry has been applied in myriad ways, each of which brings its own set of ethical considerations. One of the most important ethical considerations is the psychological impact for individuals or groups who receive genetic information from ancestry tests that may complicate or contradict family history or other sources of genealogical documentation, such as caused by issues of nonrelatedness, or claims to different national or tribal heritages.

Genealogical Information

Genealogical information is a major area in which genetic ancestry testing has been used to fill in gaps of traditional genealogical searches. While this use of genetic ancestry tests may be perceived as recreational, the results nevertheless can have serious ramifications. Some may view genetic ancestry testing as a definitive answer to their questions of heritage and identity. However, since testing results can contradict not only one another but also other genealogical information, their accuracy, assumptions, and limitations must be understood. For example, many African-Americans in search of their specific African ancestry have taken genetic ancestry tests that infer their ancestors came from particular places in West Africa, only to take another test with another company that contradicts that initial finding, presenting instead a separate ancestral connection, such as Southern Africa. The psychological impact on identity formation, as well as related group affiliations and removal from groups related to the sociocultural rules of ancestry (Royal et al., 2010), is importantly tied to this information.

Group Affiliation/Citizenship

Genetic ancestry testing may have important effects on group affiliation or citizenship in a tribe or nation. On the one hand, genetic ancestry testing might help to build connections with some groups while, on the other hand, it may sever social and cultural ties with other groups; for example, ancestry information may connect African-Americans to certain African peoples or it may lead to disenrollment of other individuals from an American Indian nation. A person's genetic test results might lead him or her to seek affiliation with a group or have additional genetic testing performed to find out specific ethnic ties to support a presumed affiliation. Others may go as far as changing their listed race or ethnicity due to results of the genetic ancestry test. On the other side, testing could also *disprove* a person's ascribed race or ethnicity and provide a challenge to their affiliation or citizenship within a group, tribe, or nation.

Human Migration Analysis

In the realm of scientific research, genetic ancestry testing primarily serves as a tool for human migration analyses. This research traces the histories of large migrations of populations of humans over time. In contrast, indigenous peoples have stories of their origins that are connected to particular places, which can relate to the *where* and *when* of their ancestral group formation. New research findings can undermine claims to territory or homelands as well as stories of group origins tied to particular geographies. These research studies have important ethical implications for individuals and groups whose samples are used for migration studies; for example, an individual from a group (such as a tribe) who participates in one type of research may inadvertently affect the whole group to whom the individual belongs because genetic information about that individual might also reveal genetic information about the whole group. On the other hand, genetic information that is revealed about a particular group can also affect individuals who identify with that group even if that individual decides not to participate in the research.

Pharmacogenomic Possibilities

Large-scale genetic ancestry testing and expansion of databases for genetic variants associated with certain populations bring with it the possibilities of applications in pharmacogenomics. Pharmacogenomics is an emerging field of study that incorporates genetic information with pharmaceutical drug information in efforts to better understand how drug interactions vary based on variation in genetic information. The promise of individualized medicine (also known as personalized medicine or precision medicine) would match up information from a patients' genetic variation with the best therapeutic options. However, to date only a few genes have been directly connected to specific disease states, such as Huntington's disease, and even fewer genes have been directly connected to better understanding effective drug interactions.

The introduction of race or other phenotypes in medical practice creates challenges in interpretation of genetic information for physicians and the public. By saying that a gene occurs more frequently in a continental population, which has correlations to racial categories, confusion with those racial categories can occur. Further, given the admixture of the overall population, physicians may have a harder time identifying members of continental population groups or even the stand-in of race, demonstrating a limited utility to the information. Even self-identification does not promise to assist in this issue, as the gene in question could occur in other modern populations or they could have no knowledge of that continental ancestry. For example, BiDil is a drug that was tested and then marketed to

African Americans, under the claim that it was more effective in that population because that population was genetically distinct, claims which are neither true nor founded in the clinical trials.

Truly personalized genomic medicine does have clinical utility, including the possibility for enhancing standard practice of care for individuals. The sequence and interpretation of one's personal genome could have promise in a healthcare system where that information can be used by physicians and clinical staff provided that the specific genes, and not substitutes for them such as ancestry, are used.

Large-Scale Projects Based on Genetic Ancestry Tests

Genetic ancestry testing has contributed to a large and profitable research and commercial sector. The most prominent projects, both public and commercial, will be reviewed here including their aims, progress, and critiques. These projects have built on the technology to discover more about variation in AIMs throughout the world, adding to the novel but limited information available after the completion of the Human Genome Project. These new projects continued in the private and public sectors, adding to the knowledge of larger connections between peoples through human migration analysis, or the study of how humans have moved throughout the globe and populated it, as well as the diversity of genetic variation.

Human Genome Diversity Project

Beginning shortly after the Human Genome Project, a separate effort called the Human Genome Diversity Project (HGDP) sought to catalog the genetic diversity of modern human populations around the world. Initially, this project received much attention and support from scientists who were interested in human genetic diversity. The HGDP organizers considered the indigenous peoples of the world as prime targets for testing because they primarily reproduced within their group and therefore were the least admixed in regards to their genetic ancestry (Cavalli-Sforza, 2005). The rationale for sampling isolated populations worldwide was to glean as much information about human genetic diversity as possible. However, HGDP organizers lost support from the very populations they wished to sample when they stressed the urgency to sample them before they *disappeared* through admixture with other populations.

In a historical account of the HGDP, Jenny Reardon's *Race to the Finish: Identity and Governance in an Age of Genomics* (Reardon, 2004) elucidates the flaws within the system including some of the researchers' beliefs in genetic purity versus genetic admixture, and the targeting of indigenous peoples. Reardon also documents the lack of community engagement. For example, HGDP researchers often quickly flew in and out of communities for genetic samples, a practice disparingly termed 'helicopter research.' Communities did not perceive benefits from participation in HGDP, and eventually many refused participation. Funding to the project from the federal level was eventually halted, though the project has continued in another form. Reardon's analysis presents why the HGDP became enmeshed in political troubles, but also concludes with the understanding that the idea of the project, to study human genetic variation, would continue and possibly much less publicly. This change prevents room for public debate and community consultation during the process.

At the end, 1064 participants from 51 distinct communities or tribes around the world were included in the HGDP database. These samples have subsequently been used by many researchers worldwide in studies on human diversity, human migration, and even in medical research. While these uses of the samples were not part of the original plans or consents, the community of scientists continues to use them for such varied research.

National Genographic Project

The National Genographic Project (NGP) aims to understand the deep ancestry of the modern human population by tracing human migrations within and out of Africa, and throughout the rest of the world. The NGP has sought to do research on a massive global scale, produce texts and films about the results, to elicit additional support and samples through a DTC effort to engage populations in developed countries to be a part of the project by sending in samples and paying for results, and puts the results into the public domain. It does so through mtDNA and NRY analyses performed as research worldwide, via population sampling and through interested individuals who submit their samples to contribute to the overall project and gain information about their ancestry. After the HGDP's controversies, the NGP took on a similar role in the world of research and genetic ancestry testing, though attempting to learn from the mistakes of HGDP, such as making sure to include indigenous peoples in their advisory board and creating tangible benefits for the indigenous populations sampled through a grants mechanism. The NGP seeks to analyze historical patterns in human genetic variation to better understand human ancestry. The NGP created the film *The Journey of Man* to showcase the project's initial findings based on Y-chromosomal DNA and their analyses of human migration based on those NRY variations. The project went on to look at the mitochondrial DNA relations in New York City, as a microcosm of the world, through *The Human Family Tree*, presenting not the current populations in their particular geographies as in the previous film but instead demonstrating the wide range of human diversity found within a specific modern geography.

Overall the NGP has come under much criticism for its practices, including lack of engagement with indigenous research subjects, conflation of modern peoples with ancestral populations, both in the rhetoric and the sampling, as well as results that reframe historical relations between groups. For example, throughout the films, mixed rhetoric demonstrates the ideological conflicts that emerge in the project, including problems to truly informed consent of participants, a master narrative of deep human relationships undermined by near racial and geographical relations, and the denial of modernity to current peoples, such as the living San Bushmen, who stand in for ancestral populations in the research (TallBear, 2007; Wald, 2006). The NGP continues despite these criticisms and has initiated a new phase known as Geno 2.0 that incorporates the use of 150 000 AIMs to provide information about regional specificity of ancestry and to allow more information than the

previous focus on mitochondrial and Y-chromosome testing had alone.

The International HapMap Project

The International HapMap Project is an effort to seek and catalog the genetic diversity and similarities of human beings. Multiple countries are contributing funding and research, including the United States, Canada, China, Japan, Nigeria, and the United Kingdom. Started in 2002, the HapMap aims to use information generated to support research in health fields by locating genes that affect disease and therapeutic drug responses as well as environmental factors. Importantly, the HapMap plans to and has been releasing its information into the public domain instead of private patent or other such limiting efforts.

Initially, the HapMap focused on four populations who were of European descent in Utah, USA, of Han Chinese descent in Beijing, China, of Japanese descent in Tokyo, Japan, and of Yoruban descent in Ibaden, Nigeria. These four populations represented European, Asian, and African ancestries and have been used as reference populations to understand the ancestry similarities and differences for other populations worldwide. Learning from the experiences from HGDP, the HapMap project organizers worked with the four communities of these populations in order to thoroughly assess informed consent before recruitment into the study. This work has now expanded to include seven additional populations, given the success of the applications of the initial data in biomedical research and promise for other groups.

DTC Testing Companies

Like the arm of the NGP's research that assists individuals who are interested in their ancestral history and in contributing to research, DTC genetic testing companies are emerging to respond to the demand of the public for ancestry information. These companies have also started to capitalize on their capacity, refining their own databases and contributing to novel research as well. Commercial DTC testing companies offer various kinds of genetic tests to map siblingship and distant kinship. These testing companies utilize their own proprietary databases of reference samples, which can lead to different tests from different companies producing different results (see section Contradictory Results). In a statement in 2008, the American Society of Human Genetics (ASHG) provided many recommendations regarding genetic ancestry testing, particularly regarding the DTC companies and other researchers who use it. The ASHG recommends that greater efforts to inform the public of the limitations of ancestry testing need to be made, more research needed to be done to prove the accuracy of the testing results, and guidelines should be developed to facilitate the return of and interpretations of results. They also call for greater accountability of the DTC companies (ASHG, 2008). In an update to this statement, a white paper came out in 2010 that further recommended that academic researchers should promote 'thoughtful and rigorous use of ancestry estimation' in their work, and that a national round table discussion should occur with DTC companies, researchers, consumers, and other key stakeholders to discuss the issues of concern and work to develop solutions (Royal et al., 2010).

Limitations

Many of the limitations of genetic ancestry testing have already been alluded to throughout this article, but the following section highlights the major areas of concern, some of which may change over time.

Databases

The current databases of samples, including mitochondrial DNA, Y-chromosomes, and SNPs, are limited in size, both in regards to the number of populations sampled and the individuals sampled within any given population to represent it and its variation. For a given geographical area, the populations and individual representatives thereof that are sampled do not reflect the entire genetic diversity of the area currently or that may have once existed in that geographical area. This limit is a particular concern with certain populations, like Native Americans, because lack of representation within the databases reflects less involvement in the research and translates to less accurate conclusions in test results. The limited size of these databases, as well as who owns which samples, can lead to misidentification via current sampling and differing conclusions when more SNPs are analyzed. For example, two different companies could have access to two vastly different databases of samples from global populations, and each could own their database and guard it as 'proprietary' information. However, a consumer who sent in a test sample to both companies could receive different ancestry estimates based on the different sets of AIMs or SNPs in their separate databases. The limited sampling of the vast amount of genetic diversity within the human population, both by number of populations and number of individuals within those populations sampled, further constrains the results available to only those gene variants present in sampled populations. From this limited sample, the probability of ancestry estimates from those populations is provided.

Ancestral Populations Derived from Modern Populations

In a related constraint, the use of modern peoples to stand in for ancestral populations itself has benefits and limits to usability. Given the recent developments in genetic testing technology and the paucity and degradation of sources of ancestral genetic data, there is benefit in using modern peoples to represent the development over time of human genetic variation. However, this analogy of modern genetic variation with ancestral, geographically specific genetic variation fails to take into account the genetic development that has occurred since the time period of the ancestral past. Again, the *when* of genetic ancestry test is important for the *where*, but that *where* is only dated in most cases to the present. It is important to recognize that the modern populations in a given geographical area have also undergone admixture and have acquired new genetic variations. They may closely resemble the ancestral populations to which they are correlated, but to what extent, there is uncertainty. While far fewer direct ancestral samples exist, such as preserved specimens or museum pieces from which DNA can be isolated and sequenced, even the use of these specimens produces additional ethical concerns about the uses of remains in ways which the original owner did not and could not have consented.

Conflation of Race and Biogeographical Ancestry

In connection to the conflation of modern peoples and ancestral populations is the conflation of the social construct of race and biogeographical ancestry. Race has been used as a proxy for biological difference, particularly in reference to phenotype differences as well as different areas of geographical origin. Biogeographical ancestry refers to the association between a geographical location and one's presumed ancestors, inferred to be related through genetic comparison with modern peoples in those particular geographical locations. Inherent to this conflation is the point that geography is socially constructed, meaning a genetic ancestry testing result that relates a proportion of estimated ancestry from Africa is understood by the recipient as related to the social construction of Africa, in modern and historical times, in regards to races, resources, and global positioning. Therefore, a result that ties someone ancestrally to any given place has to be understood in relation to how race has been used in and about that place. Given the additional layer of limitation, regarding the use of modern peoples for ancestral populations (Bolnick et al., 2007), this further conflation of race cannot be ignored. Race and its construction, as well as the influences of the genetic ancestry estimates, still permeate many lives and can lead those who receive testing results to reconsider their identity constructs despite the contrasting information, such as their communities, environments, or cultures.

Contradictory Results

Related to the limitations in the databases, when tested against different sets of reference AIMs or SNPs, some samples produce different results. In other words, in testing a given sample, one database will return ancestry estimates of a certain proportion (e.g., 50% Europe, 20% Africa, and 30% Asia) while another will return ancestry estimates of a contradictory proportion (e.g., 30% Europe, 30% Africa, and 40% Asia). While contradictory results are far less likely with mtDNA and Y-chromosome testing, they are an important concern for both research and commercial uses of genetic ancestry testing. For individuals seeking ancestry information, mtDNA and NRY only provide information about two members of a given individual's lineage. If the ancestral mix in a given person is different via different tests, what is their actual ancestral composition? How do they make sense of these contradictory results in regards to their identities? These questions demonstrate both the limits and ethical considerations that come along with using genetic ancestry testing. Beyond the individual research participant or consumer, additional questions emerge. How do researchers reconcile different results in the laboratory, particularly if these results undergird pharmacogenomics or migration study analyses? This multifaceted question emphasizes that different databases may yield different information and that using proxies for given set of variations in the genome, whether related to ancestry or not, is a poor substitute for the accurate variant.

Genetic Nonrelatedness

Another limitation, connected to certain ethical concerns, comes from the possibility of nonrelatedness revealed through genetic ancestry testing. Commonly, it is noted that nonpaternity occurs in 10% of the population, meaning that in a given group, 1 of 10 times the person who is believed to be the biological father is not such. Nonmaternity, while occurring in a much smaller portion of the population, is on the rise with innovations in reproductive technologies. This issue has been well documented in terms of its ethical constraints but also in how families given such information react, including continuing to claim kinship where they are told no genetic affiliation exists. For genetic ancestry testing, the issue with nonpaternity arises in that Y-chromosome testing and SNP analysis may reveal different deep ancestry and near ancestry than previously known, again providing information to the subject or consumer that can alter their understanding of self and have wider implications for their families and communities. Genetic tests could impact the way research participants and their families use the information. For example, a nonpaternity event in the data would provide both misleading and ethically challenging information. Further, given the commonality and possibility of genetic nonrelatedness between family members, genetic ancestry testing could be more complicated by a nonrelated event: if a sample is taken from a person who believes they have always been from a certain geographical area and a nonrelated event has occurred in their lineage (connecting them to a different geographical location), their sample may be correlated with a certain geographical location even though their mtDNA or NRY, and other genes, comes from a different geographical location.

Statistical Methods and Ancestry Estimates

A final and important limitation of genetic ancestry testing, and much genetic testing in general, is the fact that ancestry estimates are based on probability. This means that the results, or estimates, depend on the representation in the database, which also depends on the analysis of the samples, all of which can provide places for the estimates to be skewed in different directions. The statistical methods of ancestry testing carry a certain amount of uncertainty, and given the statistical nature of the estimates, definitive results beyond near ancestry are rare. Because of the inherent uncertainty in these statistical methods, researchers, test producers, and consumers all need to have a strong understanding of the probabilities. In other words, as in the contradictory multiple results, the correlation of genetic variants in a sample is made to other samples and though it might occur within multiple populations in the world, the likeliest population is chosen. The certainty of these numbers increases with the number of variants sampled as well as the robustness of the database, but they do not typically carry a 100% certainty, which would only come with an allelic variant private to a particular population present in the database. A gene variant may occur in multiple populations and therefore a test that indicates Middle Eastern descent also could have indicated Native American descent or East African descent in its place, but the probability of the variant being found in those populations is smaller.

Conclusion

This review of the terms, ethical considerations, uses and projects, as well as the limitations thereof has sought to show

the current operations of genetic ancestry testing, including why individuals, communities, and scientists have interest in its possibilities and development. Overall, the concerns regarding genetic ancestry testing must be taken seriously, and recommendations from places such as the ASHG (ASHG, 2008; Royal et al., 2010) should be followed to create better science and better understanding of that science by all involved, particularly those who receive results.

In order to avoid potential harms in the future, proper analysis, interpretation, and statements of limitations along with informed consent should occur for those participants involved in the research. Standards for DTC companies and researchers alike will help prevent contradictory information coming to the public, and the influence of that misunderstanding upon legislation, policy, or ethical conduct should also be a goal as the science moves forward. Consumers, communities, and participants must also educate themselves for the protection that such knowledge provides, through training or their own research outside of the transactions.

Future possibilities exist for the application of the testing to personal and group identity formations, kinship determinations, and group affiliation. These areas are controversial so it remain important to consider the way that the genetic ancestry testing operates within different cultures, where ideas such as race, family, and relations are socially defined. In turn, those ideas influence the uptake and understanding of information from the testing.

Genetic Approaches to Memory

Alcino J Silva, Integrative Center for Learning and Memory Brain Research Institute, UCLA Los Angeles, CA, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Genetic approaches have been extensively used in memory studies, from investigations of basic mechanisms of memory function to experiments designed to understand the mechanisms responsible for cognitive deficits. The approaches used vary and are under constant development, but can be divided into two major categories. Forward genetic studies are focused on the identification of genes responsible for memory processes of interest, including the discovery of genetic mutations that account for inherited disorders that affect cognitive function. These studies usually start with the identification of interesting memory phenotypes, and their aim is to identify and isolate the gene(s) responsible for those phenotypes. In contrast, reverse genetic studies, as the name implies, start with candidate genes that may be involved in memory, and the goal is to discover and understand the possible memory phenotypes (i.e., the function) associated with that gene. Reverse genetic studies involve the study of organisms with defined genetic changes. Although originally the goal of genetic approaches to memory was to understand the connections between genes and memory phenotypes, recently these approaches have been used to probe memory theories that go well beyond the function of the genes being manipulated.

The Role of Genetics in Biology

To understand the role of genetic studies in unraveling the mechanisms responsible for biological processes, including learning and memory, it is important to place these studies in the much broader perspective of biological investigations. The principal goal of biological studies is to understand complex phenomena such as learning and memory. Central to this process is the determination of causal connections that account for the properties of complex phenomena (e.g., learning) by the actions and functions of other relevant phenomena (e.g., genes, cells, circuits, brain regions). There are two major classes of strategies used in biological studies (including genetic studies) to test causal connections between phenomena of interest: convergence and reproducibility. All things being equal, hypotheses derived from reproducible data (i.e., reproducibility) are deemed more reliable than the alternative. Similarly, hypotheses supported by very different types of convergent evidence (e.g., elimination and overexpression of a gene) are usually considered to be in stronger footing than hypothesis derived from multiple pieces of similar evidence. Genetic approaches are capable of manipulating genes in a wide variety of ways, including studies that delete, alter, or increase the expression of a gene of interest, either in the whole organism or in a specific cell population or brain region (Silva et al., 1997). The only other biological strategy capable of manipulating molecular function is pharmacology. In this case, chemical agents are synthesized that target the function of a given biological agent (i.e., the function of a protein). Therefore, since genetics is one of only two general approaches to investigate biological function, it is easy to see why it has played a key role in every biological discipline. Beyond its key role in testing biological hypothesis (i.e., is a given kinase gene required for memory), the principal role that genetics has played in biology has been to suggest possible hypothesis or explanations of natural phenomena. Indeed, forward genetic screens have allowed biologists to make major discoveries, even in the absence of a well-delineated hypothesis.

Forward Genetics

Long before we had the ability to directly manipulate genes in animals, such as flies and mice, geneticists were busy using chemical mutagens to alter genetic information in living systems (forward genetics). The goal of classical or forward genetics, which continues to be used extensively to this day, is to identify the genes critical for biological processes of interest. The idea is that study of those genes is often a critical first hint for unraveling underlying biological processes. In forward genetic screens, animals are first exposed to a mutagen, for example, the DNA-altering compound ethyl-nitroso-urea, mated, and the progeny are screened for phenotypic changes of interest. The phenotype of a mutant is the sum total of observed biological changes caused by a genetic manipulation. Recent application of this approach in the study of mammalian circadian rhythms resulted in the identification of *clock*, a crucial link in the cascade of transcriptional events that marks molecular time in organisms as diverse as Drosophila and mice (Wilsbacher and Takahashi, 1998). Other molecular components of this pathway, such as *per*, were isolated in mutagenesis screens in Drosophila. By identifying novel and unexpected molecular components of biological processes of interest, forward genetics has often reshaped entire fields of research. At times, Science can go in circles, obsessively chasing its own tail of half-truths, incapable of escaping the gravitational pull of its worn-out paradigms. Forward genetics, in the hands of masters such as Edward Lewis (developmental mutants) and Seymor Benzer (learning mutants), has the ability to turn paradigms upside down, and initiate new lines of scientific inquiry. The key to the success of forward genetics is the design of biological screens with which the randomly mutagenized animals are tested. If the screens are too stringent, or if the fundamental biological insights underlying the screen's design are off mark, one runs the risk of ending up with empty hands, or even worse, with a number of misleading mutants. In contrast, nonstringent designs lead to overwhelming numbers of nonspecific mutants that are essentially useless.

The First Screens for Learning and Memory Mutants

Seymor Benzer and colleagues working with Drosophila at the California Institute of Technology designed the first successful screen for learning and memory mutants in the 1970s (Dudai, 1988). Benzer and colleagues developed a behavioral procedure with operant and Pavlovian components. During training, the flies were allowed to enter two chambers, each with a different odorant, but they only got shocked in one of the chambers. During testing, approximately two-thirds of the trained flies avoided the chamber with the odorant that previously had been paired with shock. With this procedure, Benzer and colleagues tested a number of Drosophila lines derived from flies treated with ethylmethane sulfonate. The first mutant line isolated from this screen was *dunce* (Dudai, 1988).

Remarkably, three out of the four learning and memory mutations, first discovered in genetic screens in *Drosophila*, code for members of the cAMP-signaling pathway. For example, *dunce* lacks a phosphodiesterase that degrades cAMP. Importantly, these findings have recently been extended into vertebrates, where electrophysiological and behavioral studies have confirmed the critical importance of cAMP signaling to learning and memory (Silva et al., 1998). Remarkably, in the early 1970s, Eric Kandel and his colleagues at the Colombia University also found evidence for the importance of cAMP signaling in learning and memory with a completely different approach. They used a reduced cellular preparation to study sensitization, a nonassociative form of learning, in the sea snail *Aplysia* (Byrne and Kandel, 1996). They also found that sensitization depends on cAMP signaling. This is a fascinating example of convergent evidence in science, but it also serves to illustrate that genetics, like any other tool in science, is most successful when used in parallel with other approaches. The persuasive power of convergent evidence cannot be overemphasized. Besides identifying new genes, genetics can also be used to test hypothesis about the function of cloned genes (reverse genetics).

Reverse Genetics

In classical genetics, an interesting phenotype is usually the driving force behind the molecular experiments required to identify the underlying mutant gene(s). In contrast, in reverse genetics, the interesting molecular properties of a gene usually drive the generation and study of the mutant animal (hence, the word reverse). It is now possible to delete and add genes to many species, ranging from bacteria to mice. For example, mice can be derived with the deletion (knock-outs) or overexpression (transgenics) of almost any cloned gene. These manipulations can involve whole genes or they can target specific domains or even single base pairs.

To generate knock-out mice, the desired mutation is engineered within the cloned gene, and this mutant DNA is introduced into embryonic stem (ES) cells. Since ES cells are pluripotent, they can be used to derive mice with the genetically engineered lesion. For that purpose, they are injected into blastocysts (early embryos), and the blastocysts are implanted in host mothers. The resulting chimeric (having mutant and normal cells) offspring are then mated to obtain mutant mice. In contrast, transgenic mice are derived by injecting the pronuclei of fertilized eggs with a DNA construct carrying a gene of interest under the regulation of an appropriate promoter. The injected eggs are transplanted into pregnant females and some of the resulting progeny will have the transgenic construct inserted randomly in one of its chromosomes.

With classical knock-out and transgenic techniques it is not possible to regulate the time and the regions affected by the mutation/transgene. However, recent techniques promise to circumvent these limitations with a variety of techniques. For example, the expression of the gene of interest can be regulated by gene promoters that can be controlled by exogenously provided substances, such as tetracycline derivatives (Mayford et al., 1997). Alternatively, it is also possible to regulate the function of a protein of interest by fusing it with another protein that can be regulated by synthetic ligands, such as tamoxifen (Picard, 1993). For example, our laboratory recently showed that a transcriptional repressor called CREB can be activated at will when fused with a ligand-binding domain (LBD^m) of a modified estrogen receptor. Addition of tamoxifen (the ligand of the modified receptor) activates the $CREB^r/LBD^m$ fusion protein. It is important to note that irrespective of the exact method used, the general idea of reverse genetic studies is that the function of a gene can be deduced from the phenotype of the mutant animal.

Knock-outs, Transgenics, and Learning

The first knock-out/transgenic studies of learning and memory analyzed mice with a targeted mutation of the α isoform of CaMKII (Grant and Silva, 1994). Pharmacological studies had previously shown that this family of calcium calmodulin-induced kinases present in synapses were required for LTP, a stable enhancement in synaptic efficacy thought to contribute to learning and memory. Remarkably, deleting αCaMKII resulted in profound deficits in hippocampal LTP and in hippocampal-dependent learning and memory. Additional studies showed that either the overexpression of a constitutively expressed form of the kinase, or a mutation that prevented its autophosphorylation, also disrupted LTP and learning. Importantly, studies of hippocampal circuits that fire in a place-specific manner (place fields) showed that these CaMKII genetic manipulations disrupted the stability of these place-representations (but not their induction) in the hippocampus. Altogether, these studies suggested the provocative hypothesis that this kinase is important for the induction of stable synaptic changes, that the stability of synaptic changes is crucial for the stability of hippocampal circuits coding for place, and that these circuits are essential for spatial learning (Elgersma and Silva, 1999). Even this very abbreviated summary demonstrates that these studies went well beyond gene function. Instead, they used mutations to test hypotheses that connected molecular, cellular, circuit, and behavioral phenomena. Although it is reasonable to claim that the αCaMKII has a direct role in the regulation of synaptic function (for example, by phosphorylating glutatmate receptors), it is more problematic to argue that the kinase is regulating spatial learning. There are a lot more

phenomenological steps between kinase function and the animal's ability to find a hidden-platform in a water maze than between the biochemical properties of this kinase and its role in synaptic plasticity. By comparison, it is easier to see how the stability of place fields in the hippocampus could be an important component of hippocampal-dependent spatial learning.

Common Concerns with the Interpretation of Transgenic/Knock-out Studies

Despite the power of genetics there are a number of concerns that must be kept in mind when using genetic approaches. One of the most commonly discussed is the possibility that developmental effects or any other change caused by the mutation preceding the study could confound its interpretation. Another pertains to the possible effects of genetic compensation. Since proteins do not work alone, but instead function in highly dynamic networks, it is often observed that specific genetic changes lead to alterations/compensations in the function of other related proteins. A related concern pertains to genetic background. Extensive studies have shown that the genetic background of a mutation has a profound effect on its phenotype. The concerns listed above are not limitations of genetics, but simply reflect the properties of the biological systems that genetics manipulates. At the heart of many of the concerns described above are two misconceptions concerning the nature and organization of biological systems.

First, genetics is essentially a lesion tool. As other lesion tools, it cannot be used in isolation. To establish causal connections between any two phenomena (A and B) in science, it is never enough to lesion A and document the alteration of B. As described above, it is also critical to fulfill three other criteria: first, A must be observed to precede B. Second, triggering A should result in B, finally, it is essential to have a clear hypothesis of how A triggers B. Fulfilling one or two of those four criteria is simply not enough to establish a causal connection between A and B. Therefore, although studying the effects of a deleted protein is an important component in determining its function, it is by no means sufficient.

Second, biological systems are dynamic and adaptive, and therefore, the lesion of any one component is always followed by changes in several other components. Although it is often a helpful simplification to think of biological components as independent functional units, it is important to remember that they are not. Thus, it is hardly surprising that the effect of a mutation is dependent on biological variables such as genetic background.

The Future of Genetic Manipulations

In the near future, it will be possible to delete or modify any gene, anywhere in most organisms of interest, and at any time of choice. Additionally, more powerful forward genetic strategies will allow the isolation of entire pathways of genes involved in any neurobiological phenomenon of interest, including learning, attention, emotion, and addition. In parallel with expected advances in genetics, there will also be advances in the methods used to analyze mutants. These advances are just as critical to genetic studies as advances in genetic methodology. For example, imaging the brain of mutant mice may yield insights into how molecular lesions affect the function of brain systems. Most genetic studies of learning and memory in mice have focused on the relationship between cellular phenomena (i.e., LTP) and behavior. Advances in small animal magnetic resonance imaging may enable the kind of functional system analysis in the brains of mutant mice that have so far only been possible in large primates. Similarly, multiple single-unit recording techniques are starting to yield systemwide snapshots of circuit activity in the brains of mutant mice. At a molecular level, small-size positron emission tomography devices will allow the imaging of molecular function in leaving animals, such as mice. For example, it may be possible to image the activation of a receptor, such as the dopamine receptor, during learning or memory. Microarray techniques and other molecular cloning approaches will allow the identification of gene profiles in mutant mice. These molecular profiles will be critical to delineating the molecular changes behind the expression of a mutant phenotype. It is important to note that genetics allows us to reprogram the biology or organisms. The finer and more sophisticated the phenotypic and genotypic tools that we have at our disposal, the deeper we may be able to probe the magical natural programs embedded in our genes.

Abstract

Genetic counseling refers to the totality of activities that (1) establish the diagnosis of genetic disease, (2) assess the occurrence risk, (3) communicate to the patient and family the chance of recurrence, (4) provide full and unbiased information within a caring relationship regarding many problems raised by the disease and its natural history, including the potential medical, economic, psychological, and social burdens, and (5) provide information regarding the reproductive options. The understanding and goals of genetic counseling as they evolved over the last century exemplify the substantial shift in understanding, determining, diagnosing, and handling of hereditary/genetic risks. At present, nondirective concepts have found broad, though not universal, acceptance.

Genetic counseling is one of the most important direct applications of human genetic knowledge. Genetic counseling refers to the totality of activities that (1) establish the diagnosis of genetic disease, (2) assess the occurrence risk, (3) communicate to the patient and family the chance of recurrence, (4) provide full and unbiased information within a professional caring relationship regarding many problems raised by the disease and its natural history, including the potential ethical conflicts as well as the medical, economic, psychological, and social burdens, and (5) provide information regarding the reproductive options to be taken, including prenatal diagnosis, and referral of patients to the appropriate specialists. Genetic counseling should offer guidance but will allow those being counseled to arrive at their own choices, both before and after genetic procedures (Vogel and Motulsky, 2010; World Health Organization [WHO], 2012).

Paradigm Development and Concepts of Genetic Counseling

Prescientific knowledge of heritability in humans dates back to the early Greek physicians and philosophers, who presumably dispensed practical advice to individuals and couples as to how to use such knowledge (Vogel and Motulsky, 2010). The idea of an improvement of humankind by deliberate mate selection was a major aspect of ancient and Renaissance state and social utopias [Plato, *Politeia* (ca. 374 BC); Thomas More, *Utopia* (1516); Fra Tomaso Campanella, *The City of the Sun* (1623)]. In the medical literature of the eighteenth and nineteenth centuries, reports on the familial recurrence of particular disorders began to accumulate. An early and noteworthy example is the book by the English physician Joseph Adams (1756–1818), *A Treatise on the Supposed Hereditary Properties of Diseases* (1814), which attempts to lay out the fundamentals of genetic counseling for families affected by a genetic disorder.

Toward the end of the nineteenth century, two paradigms established human genetics as a science. Gregor Mendel (1822–84) originated the concept of the gene as the basic factor of inheritance (1866), while Francis Galton (1822–1911) introduced statistical methods to investigate and interpret the familial clustering of traits and thus founded the biometrical paradigm. Until the present, biometrics and Mendelian genetics have remained the basis of risk determination as the naturalistic component of genetic counseling. Galton coined the term 'eugenics' to mean the improvement of a population through measures to enhance propagation of individuals with supposedly high genetic qualities (positive eugenics) and discourage reproduction in those with undesired characteristics (negative eugenics). In Germany, around the turn of the twentieth century, Wilhelm Schallmeyer (1857–1919), Alfred Hegar (1830–1914), and Alfred Ploetz (1860–1940) developed the idea of negative eugenics–a concept of decreasing the number of offspring of individuals with supposedly below-average hereditary qualities, or of preventing congenitally diseased individuals from reproducing altogether, with the aim of improving the gene pool of future generations and especially that of the presumed superior Nordic race (see Ploetz, 1895).

In many countries during the first half of the twentieth century, positive and negative eugenics formed the ideological basis of state-enforced measures to exert reproductive control over individuals. Between 1911 and 1930, 24 U.S. states proclaimed sterilization laws, and eugenic thought also played a role in the enactment of restrictive immigration laws. In Europe, Denmark was the first country to proclaim a Law on Genetic Hygiene (1929), in which voluntary sterilization for genetic reasons was regulated. In Germany, the Law for the Prevention of Congenitally Diseased Progeny (1933), followed by a series of other laws and decrees, mandated and organized the sterilization of individuals with certain diseases, which were thought to be genetically determined. In Germany, eugenics, racial hygiene, and National Socialist ideology formed a gloomy alliance. The involvement of German geneticists in coercive measures and eventually the Holocaust to sections of the population that were declared to be inferior has been well documented by Müller-Hill (1997). It is beyond doubt that this historical burden strongly influences the current debate on ethics and genetics in Germany and elsewhere.

From about 1930 onward, the eugenic movement outside Germany began to lose power, but it was not until the 1950s that the population-directed eugenic orientation was slowly replaced by a medically oriented practice with genetic disease prevention as a major focus. Nevertheless, eugenic thinking, whether acknowledged or not, has continued to play a role until the present time, especially outside the Western world (Wertz, 1997). When, in 1947, Sheldon Reed coined the term 'genetic counseling,' it became clear that eugenics and what was then understood to be genetic counseling, were different entities. One historian (Stern, 2005) states that rather than clinical genetics being a complete departure from the eugenics movement, many of the concepts were retained, but the service was delivered in ways that enabled individual choice to be paramount. Clinical genetics differs in this sense from public health genetics, the focus of which is the improvement of the health of large populations in any public health setting. According to Reed, "genetic counseling is a type of social work entirely for the benefit of the whole family without direct concern for its effect upon the state or politics" (1974). This definition marks a change of paradigm in applied human genetics, away from the concern about the genetic makeup of the population and toward the attitude that decision making with regard to genetic risks should be left to the individual, even if this may create or increase social costs or be perceived as somehow worsening the gene pool. Thus, one of the fundamental ethical principles in medicine–respect for the autonomy and self-determination of persons–is also the cornerstone of genetic counseling.

Genetics in relation to human health has thus gone through three overlapping historical phases (Table 1). First, the eugenics phase, mainly rooted in England, the United States, Scandinavia, and Germany, was based on the social and biological utopia of general mental and physical health and the optimization of humankind. In order to attain these goals, depending on political circumstances, directive measures including direct and indirect coercion were applied. Eugenics was scientifically ill founded, and the definition of inferior or superior genetic qualities was a matter of ideology.

Second, the preventive-medical phase laid its emphasis on reducing individual suffering through prevention of genetic diseases and disabilities, in order to economize rare social welfare and medical resources. It was founded on the rational calculation that any means toward that end would find acceptance as being in the immediate interest of the individual. Strategies were those of benevolence, authority, and paternalism.

Third, in the biopsychosocial phase, the focus of genetic counseling is to help the individual or the family to manage a problematic situation caused by genetic disease. The basis of this help is a complex interaction between the counselor (a specialized physician or a nonmedically trained expert) and the client (patient) in a nondirective process of communication. Help is provided with the understanding that genetic diseases are often associated with special psychosocial problems and ethical conflicts that should be addressed individually. Thus, any direct or indirect coercive influence is to be avoided.

Nondirectiveness became a basic concept of genetic counseling (Wertz, 1997). However, genetic counselors have questioned the value of nondirective counseling from the patient's perspective for several decades, as it was interpreted by some as an inability to support patients in their decision-making process, rather than a lack of coercion (Wolff and Jung, 1995; Kessler, 1997). Patients frequently seek some reassurance from the counselor that the course of action they propose to take would be reasonable, and good counseling practice includes the exploration of the values and beliefs of the client and support for a decision that would be consistent with those values (Weil et al., 2006; Bartels et al., 1997). In addition, it should be clear that better health outcomes are likely to ensue from particular decisions, for example, having a genetic test that would clarify the need for invasive clinical surveillance (Schwartz et al., 2012). Under these circumstances, it is clear that provision of accurate information about potential benefits or disadvantages of testing should be explained as part of the genetic counseling process and that identifying health benefits should not be seen as coercive. However, coercion may exist where the counselor clearly tries to influence the patient to confirm to his or her own views.

The history of genetic counseling shows that its purpose has always been value-determined and has never been seen outside the context of social politics in which it was embedded. In countries that acknowledge human rights as defined in the democratic state theories of the eighteenth century, the only defensible position is that of the autonomy of the individual to make decisions regarding genetic counseling and genetic diagnosis, and to draw consequences for life and family planning.

The health care system, on the other hand, carries the ethical obligation to provide full information and the tools that may enable the individual, depending on the state of knowledge, the emotional situation, and moral positioning, to make use of that information.

Excursus: Ethics and Genetic Counseling: The Respect for Personal Autonomy

Today the term 'eugenics' is sometimes used to describe the cumulative result of individual choices after genetic counseling, especially in view of reproductive choices. The decreasing

Table 1 Paradigm shifts in applied human genetics

Paradigm	*Basis*	*Goal*	*Measure*
Eugenics	Emotionally influenced social utopia	Improvement of the gene pool	Directiveness, compulsion, coercion
Prevention	Rational calculation	Reduction of individual suffering, economic distribution of resources	Paternalism
Psycho(socio)-biology	Complex interaction between counselor (doctor) and client (patient)	Help in individual decision making	Empathy, nondirectiveness

prevalence of births of children with Down syndrome in western Europe, especially in the UK, may be regarded as a result of individual choices to undergo prenatal diagnosis and subsequently to terminate a pregnancy after a positive test result. Whether this type of individual eugenics is a benign development and socially desirable has been discussed with some controversy by Wertz (1998). Critics argue that free, autonomous choices (after genetic counseling) not only depend on surrounding social, cultural, and other factors, but also on the full and honest presentation of information in genetic counseling–that is, on access to valid information. Informed consent can only be said to exist under three conditions: The patient is given the appropriate information; the patient is competent to make the decision; and there is no coercion involved (Beauchamp and Childress, 2001). In the absence of correct and unbiased information, free choices are not possible and are compromised, and information and genetic counseling become a means of furthering the attitudes and goals of health professionals. A worldwide survey of 2091 genetics professionals in 36 nations conducted by Wertz (Nippert and Wolff in Germany) suggests that eugenic thought underlies the perception of the goals of genetics and genetic counseling in many countries. In developing nations of Asia and eastern Europe especially, directive counseling is practiced to influence individual decisions. Intentionally pessimistically biased information is routinely provided after positive results from prenatal diagnosis in order to avoid the birth of affected children (Wertz, 1998; Cohen et al., 1997). The data from this survey suggest that the concept of nondirective counseling found in English-speaking nations and western Europe is an aberration from the rest of the world.

Indications for Genetic Counseling

In medicine in general, a therapeutic activity is 'indicated,' when, after weighing the risks and benefits, it appears medically required. This definition is hardly applicable to genetic counseling because the recognition of risks and benefits of knowledge, as well as any actions that may result from such knowledge, will emerge only in the counseling process itself, and their appraisal is often more strongly determined by individual life circumstances than by medical judgment. On the other hand, the professionalization of genetic counseling as a specialization within medicine, and the need for correctness and completeness of any medical advice, have brought about a core service that every counselee may duly expect to receive: a scientifically founded statement regarding the etiology and the (recurrence) risk of a genetic condition, comprehensive information and counseling regarding diagnostic options, and referral to preventive, therapeutic, and/or socially alleviating measures.

Generally speaking, an indication for genetic counseling is given whenever an individual regards it as a means to help solve a personal problem related to an existing or suspected genetic risk. Table 2 summarizes the most frequently encountered situations. With the increasing awareness and availability of pre- and postnatal methods of genetic diagnosis, individuals may find themselves unexpectedly receiving risk information about conditions of which they had previously been unaware.

Table 2 Indications for genetic counseling

1. Birth of a child with congenital disease or disability
2. One or more relatives suffering from (suspectedly) genetic disease or disability
3. Affected counselee
4. Consanguineous couple
5. Recurrent miscarriage
6. Infertility
7. Mutagenic influences
   - 7.1 Advanced maternal age
   - 7.2 Pre- or postconceptional mutagen exposure
8. Teratogenic exposure
   - 8.1 Infections
   - 8.2 Drugs
   - 8.3 Alcohol
   - 8.4 Radiation

Concerns, including moral doubts, may have been raised, for example, by offers of prenatal screening (maternal serum marker and ultrasound screening), or carrier detection, within or outside the framework of a defined screening program because such offers may bring up the question of termination of the pregnancy.

The Counseling Process

According to an initial definition issued by an Ad hoc Committee on Genetic Counseling of the American Society of Human Genetics, genetic counseling is a communication process that:

> …deals with the human problems associated with the occurrence or risk of recurrence of a genetic disorder in a family. This process involves an attempt by one or more appropriately trained persons to help the individual or the family to 1. comprehend the medical facts, including the diagnosis, the probable course of the disorder, and the available management; 2. appreciate the way heredity contributes to the disorder and the risk of recurrence in specified relatives; 3. understand the options for dealing with the risk of recurrence; 4. choose the course of action which seems appropriate to them in view of their risk and their family goals and act in accordance with that decision; 5. make the best possible adjustment to the disorder in an affected family member and/or to the risk of recurrence of that disorder. (Fraser, 1974; Ad hoc Committee on Genetic Counselling, 1975)

However, developments in the profession resulted in a new definition of genetic counseling that involves an approach aimed at integrating the genetic information with other aspects of the client's life and encompasses more of the educational aspects of the activity. According to members of a task force of the National Society of Genetic Counselors (Resta et al., 2006, p. 77),

"Genetic counseling is the process of helping people understand and adapt to the medical, psychological and familial implications of genetic contributions to disease. This process integrates the following:

- Interpretation of family and medical histories to assess the chance of disease occurrence or recurrence.

- Education about inheritance, testing, management, prevention, resources and research.
- Counseling to promote informed choices and adaptation to the risk or condition."

The counseling process is usually initiated by clarifying the counselee's motivation for consultation. What is the background to the problem, and what are the expectations? The counselor should explain, in general terms, what genetic counseling can achieve and where its limits lie. This is important because expectations are frequently unrealistic. It needs to be explained, for example, that it is technically not possible to exclude any kind of genetic risk or to guarantee a healthy child. The next step is to record the personal and family medical history in the form of a genealogical tree, encompassing at least all first- and second-degree relatives. This is followed by providing the family with information regarding the most important medical facts concerning the disease in question (natural history of the disease, the likely degree of suffering it may confer, its treatability) as well as the likelihood of its occurrence or recurrence. It is important to give unbiased, objective information. During the later phases of the counseling process, the counselor will often return to this information to relate it to the personal views of the counselee.

The 'prior' risks for a genetic condition as deduced from its pattern of inheritance (monogenic dominant or recessive, autosomal or sex-linked, co-determined by several genes and/or the environment) may be modifiable by genetic diagnostic tests, other clinical test results, or other information (such as number of unaffected children in a family), so that a more precise risk figure emerges. Ever more often, with the near completion of sequencing and functionally annotating the human genome (Human Genome Project, 1997) and concomitant technical developments becoming routine practice, firm confirmation or exclusion of carrier status for any particular genetic disposition will be the rule rather than the exception. Nevertheless, the phenotypic outcome will often be variable, due to environmental factors, complex interactions between genes, and other 'non-Mendelian' genetic and epigenetic factors such as imprinting. In the counseling process, the resulting uncertainty needs to be explained and worked upon with great care. Without thoroughly understanding the chances and limits of genetic testing, an informed consent to any such procedure cannot be attained. Informed consent is generally held to be the prerequisite for any genetic testing, but as previously stated, the need for nondirectiveness in all situations is now questioned, even by potential users of the health service. A study by Martin et al. (2010) indicated that discussion among members of the public was more focused on individuals making choices rather than the principle of informed consent, although they did emphasize public education was a prerequisite to choice. They also expressed concern that coercion to be tested might stem from other members of family, rather than from health professionals.

During the counseling process it may be necessary to make a physical examination of the counselee and/or of family members in order to search, for example, for early signs of a late-onset disorder or microsymptoms of a disease. The impact of such an examination needs to be explained beforehand because counselees and their family members may wish to help clarify genetic risks for others, but not necessarily for themselves. It is sometimes difficult to decide to what extent information from the family history (such as risk for another condition that is apparent to the counselor but unsuspected by the counselee) needs to be discussed, if this information has not been central to the counselee's motivation for consultation. This is particularly delicate when no therapeutic or preventive options exist. Where these options do exist, however, the counselee has a right to comprehensive information and counseling.

The Determination of Genetic Risks

The determination of genetic risks in any individual case is the essential component of genetic counseling. It requires expertise in general and human genetics, including formal (mathematical) genetics, population genetics, and clinical genetics, as well as an awareness of novel developments, especially in the differential genetic diagnosis (attainable in this fast-moving field only through continuous further self-education). In the following discussion, we provide a summary of the most important groups of conditions in which a risk assessment is often sought and present a brief outline of risk provision. Often, the prior genetic risks need to be modified by using information from the pedigree or genetic tests (conditional probabilities). By employing Bayesian methodology, this information can be used to arrive at posterior (final) risks (Harper, 1998).

If a disease is (mainly) due to the effect of a single gene, the phenotype may be inherited in a recessive or a dominant fashion. The disease may manifest itself in a sex-dependent way, if the causative gene is not located on the autosomes (the chromosomes shared by both sexes in equal number) but rather on the sex chromosomes (X and Y). In an autosomal-recessive condition, the recurrence risk in a sibship is 1/4, but usually low (less than 1%) for second-degree relatives. If a parent has an autosomal-dominant condition, there is a 50% chance that each child will also carry the disease-causing mutation. If neither parent has a condition that is known to be autosomal-dominant, the recurrence risk in a sibship is usually negligible, because the presumption is that a spontaneous mutation has occurred in the germ line leading to the affected individual. In X-linked recessive disease, if the mother is a carrier, half of all her sons will develop the full clinical picture, and half of her daughters will be carriers. Mothers and daughters are usually unaffected or exhibit symptoms to a lesser degree (due to nonrandomness of X-inactivation during early development). In Y-linked disease (such as subfertility), the trait is passed on from fathers to sons.

In both recessive and, most notably, dominant conditions, the inheritance patterns may be obscured by variable penetrance (proportion of carriers manifesting the phenotype at all) and expressivity (degree of disease severity). Greatly reduced penetrance and expressivity–that is, where only a small fraction of carriers suffer from the condition–leads to the concept of genetic predisposition (susceptibility) for disease, which may be modulated by other genes or environmental factors. Polygenic and multifactorial inheritance are the etiology of most of the common diseases (such as coronary heart disease, obesity, and diabetes mellitus) and the majority of cases of birth defects. In these categories, empirical risk figures apply.

Numerical chromosomal aberrations are usually sporadic, with a low empirical recurrence risk in a sibship, but they may also run in families (e.g., structural aberrations, such as translocations, which may be inherited as balanced or unbalanced in offspring in a more or less apparent Mendelian fashion).

Genetic Counseling in the Social Context

How has genetic counseling and its supposed high standards fared in common practice? Throughout the world, the professional identity and training of providers of genetic counseling services varies. In Germany, for example, most counseling services are provided by physicians who are specialists in medical genetics (Nippert et al., 1997), while in many others (such as the United States, Canada, South Africa, Japan, France, the Netherlands, and the UK) a multidisciplinary team (including medical doctors, genetic counselors, and genetic nurses) is involved. While genetic counseling as an activity can be provided by professionals from a number of backgrounds, genetic counselors are specifically trained nonmedical professionals. A recent overview of the genetic counselor and genetic nurse in Europe (Cordier et al., 2011) indicated that differences in professional backgrounds and relative numbers of practitioners existed between countries. For example, in some European countries (e.g., France, the UK, Romania, Spain, and Portugal), genetic counselors are educated through a master's program in genetic counseling, while in others no such program exists and practitioners may have a wide range of backgrounds, including laboratory genetics, nursing, or social work. In Europe, only the UK has a national system for registration of genetic counselors. In the United States and Canada specialist genetic counselors must complete an approved master's degree in genetic counseling and be certified by the American Board of Genetic Counseling or the Canadian Association of Genetic Counselors, while a similar system exists in Australia and South Africa.

Despite differences in education and background, a survey of 216 European genetic nurses and counselors showed that clinical practice was remarkably similar across countries (Skirton et al, 2013). The majority of respondents stated that they alone or with a medical colleague took responsibility for making the first contact with the family (87.9%), drawing the pedigree (85.2%), explaining a genetic test to the patient (79.5%), and providing psychological support through the testing process. Over 81% managed some cases without the input of a medical doctor.

While published policies and guidelines on provision of genetic services have existed for some time (Fraser, 1974; German Society of Human Genetics, 1996; Andrews et al., 1994; WHO, 1998; Fryer and Lister Cheese, 1998; Holtzman and Watson, 1997), the type of information and the way information was communicated was found to vary within and between countries, and standard practices developed only slowly. Obviously, genetic counseling practices were shaped by the characteristics of the various health care systems, as well as by the personal characteristics of the counselor, such as sex, professional expertise, and type of employment. The process and outcomes of genetic counseling have been documented by a few empirical studies (Sorenson, 1992). Initially, outcomes were defined primarily on the basis of patient knowledge and patient satisfaction (Clarke et al., 1996), but this has altered in recent years. Researchers now approach the topic in a holistic manner to determine the outcomes of importance to patients and professionals (Skirton, 2001, Skirton et al., 2005; McAllister et al., 2008a; 2008b). These studies have shown that genetic counseling can help individuals adapt psychologically to their circumstances and enhance their sense of empowerment.

Concern has been voiced that in the future more counseling will be provided by professionals not trained in genetics. Although there is insufficient empirical evidence that genetic counselors successfully achieve autonomous, informed decision making, research from Europe and the United States suggests that nongeneticists do not set a high value on providing information that allows informed decision making before undergoing tests such as prenatal diagnosis (Dodds, 1997) or predictive testing (Burke, 2004).

In recent years, an initiative to harmonize the standards and practices of genetic counseling was started within the EU-funded Network of Excellence 'Eurogentest' (www.eurogentest.org). It included a survey of legislation regarding genetic counseling in European member states (http://www.eurogentest.org/professionals/info/public/unit3/regulations.xhtml; Soini (2012)), a survey of international bodies including political institutions, professional organizations, ethical boards, and patient associations (http://www.eurogentest.org/web/files/public/unit3/summaryofguidelinesMay06.pdf), and a survey among European National Societies of Human Genetics (http://www.eurogentest.org/web/files/public/unit3/Results_of_survey_1_WP_3-1_Dec06.pdf). What emerged from these activities were the Eurogentest "Recommendations for Genetic Counseling Related to Genetic Testing" (http://www.eurogentest.org/professionals/info/public/unit3/final_recommendations_genetic_counselling.xhtml). These activities respond to a widely felt need for standardization of genetic counseling practice, thereby improving the quality of genetic counseling especially in the context of old and new genetic testing options.

With the development of more new molecular tests, implementation of these tests in various fields of medicine is expected to drive the diversification of genetic counseling practice. While at present many general health care providers and nongenetics specialists do not have sufficient professional education and expertise in genetics, molecular testing, and genetic counseling to perform this task as shown by the European study on genetics education (Harris et al., 2006), there are certainly specialists in other areas who are providing effective and appropriate genetic counseling services and genetic testing in relation to their own fields. For example, in oncology, cardiology, and diabetes care, presymptomatic testing of those at risk has enabled resources, clinical surveillance, and treatment to be targeted at those who will benefit from them.

However, there is an issue around provision of education for providers via medical curricula and continuing education. Genetic specialists are arguably the most valid source for providing the needed expertise and information for their medical colleagues to facilitate their understanding of basic genetic principles and the application of molecular testing, including pre- and post-test counseling, in clinical practice.

However, the more genetics becomes part of general medicine and the more genetic testing is introduced into the various specialty areas, the more the task to provide information and to interpret test results will fall on primary care physicians and nongenetics specialists. Indeed, it could be claimed that primary care is the appropriate setting in which to utilize the power of genomic tests to create more truly personalized medicine (Gibbon, 2009). This requires greater genomics literacy among those health professionals in both secondary and primary care.

In its Federal Act on Genetic Testing put into force in 2010, Germany, for example, has not only implemented a legal obligation for all medical doctors to recommend to their patients genetic counseling in the context of genetic testing but also to undergo training in genetic counseling themselves (via continuous medical education measures), unless they refer to specialized genetic counselors. Given that genetic test utilization is rising steeply (Schmidtke et al., 2005) and genetic centers are sparse and understaffed, such referrals may become restricted to complicated cases, while the majority of genetic counseling may be given from nongenetic specialists.

The European Society of Human Genetics has recently published "Core Competences in Genetics for Health Professionals in Europe" (https://www.eshg.org/139.0.html), in which many of the skills currently expected from specialized genetic counselors are stated to be core competences in primary and secondary nongeneticist specialists' care. These competences are already being adopted for use in preparing specialists in other settings (e.g., nurses working in hemoglobinopathy or inherited bleeding disorder clinics in the UK) to offer appropriate care to patients. Importantly, the core competences stress the need for appropriate information, patient choice, and ethical practice, whatever the clinical context in which genetic health care is offered.

Most likely, the future of genetic testing and counseling will be shaped by economic interests; there is of course the need for financial returns on heavy investments made in the field of molecular testing, by reimbursement practices, and by the extent to which national health care policies will encourage genetic testing. It remains unclear whether the main ethical concepts attached to genetic counseling, such as nondirectiveness, individual autonomy, and greater equality in the doctor–patient relationship, will survive or will wither away during the integration of genetic tests into routine medical practice. Hopefully, genetic counseling will retain some of its best elements, namely, respect for patients' rights to valid, nonslanted information and for patient autonomy in decision, making.

Genetic Engineering

David J Harris, Boston Children's Hospital, Boston, MA, USA

Abstract

The techniques of genetic engineering have been used to determine elements of the genome of an organism, as well as copy, isolate, and identify single genes in many species including our own. Transferring human genes to other organisms allows investigators to understand the proteins and study the pathogenesis of disease. This approach is being used to either treat diseases by gene therapy or identify targets for drug development.

The term 'genetic engineering' stands for human alteration of the genetic code of an organism, so that its biosynthetic properties are changed. The major applications are for the industrial production of desired peptides or proteins or to alter the biological capabilities of the organism. These techniques have been used to develop crops with agronomically useful changes, such as pest resistance and ripening properties that allow for shipment. On the medical front, peptide hormones such as insulin have been produced as well as larger proteins to perform essential functions in individuals with disorders caused by mutations that act by either stopping the synthesis of a protein or producing an ineffective structure. There is a lot of interest in developing such products.

By silencing genes in experimental organisms, as well as by producing animal models of human disease, we have gained information about the pathogenesis of structural and biochemical disorders. Single human genes that follow classic Mendelian patterns are still being identified, however, more attention is being paid to complex traits. Most investigators agree that behavioral phenotypes fit this category.

Biological Background

The technology has developed in the context of the understanding of genetics. In order for a species to survive and evolve, variability must be produced and maintained in the population. One of the mechanisms that produces such variability is recombination. Information for the amino acid sequence of a number of peptides as well as the controlling mechanisms for regulating their synthesis are inherited together on a single chromosome. In diploid organisms, exchanges between homologous chromosomes are an important source of variation. This process occurs in the context of DNA replication, including the enzymatic unwinding of the double helix and synthesis of the new, complementary chain of nucleic acids.

Cellular properties may be altered by external mechanisms. One of the first systems that was extensively studied, and provided the tools that are currently used, is the phenomenon of infection of bacteria by bacteriophages, the bacterial viruses. These are the usual steps in protein synthesis. The message is coded in the DNA sequence. It is then transcribed into the sequence of the intermediate messenger RNA molecules, and then translated into protein. In the 'lytic cycle,' the viral DNA instructions are used to synthesize new viral DNA and protein that can assemble into new viral particles that destroy the cell and are then released into the environment to infect other host cells. In the 'lysogenic cycle,' the DNA of the virus integrates into the host DNA. In addition, there are a number of other particles called plasmids, which can transfer genetic information from one bacterium to another. They are small, circular DNA molecules that replicate independently of the DNA of the host bacterium. Their role is particularly prominent in the transmission of antibiotic resistance. The life cycles of most animal viruses are similar to the lytic cycle of bacteriophage, however, there are a number of viruses that can become latent. There are also agents like the retroviruses, whose genome gets transcribed into the host DNA, thereby changing cellular properties. Some of these agents will also incorporate host DNA into their sequences and transmit this sequence into a new host.

The tools that allow us to transfer genes from one organism to another are the restriction endonucleases. These enzymes are found naturally in bacteria and protect them from infection by breaking down foreign DNA. They are chemically very specific, only working on specific palindromic sequences. Consequently, the kind of infection discussed in the last paragraph can only occur if the bacteriophage sequence does not contain elements that will be broken down by the host bacterial system of endonucleases. A number of different enzymes are found in different bacterial species, and the enzymes referred to by an abbreviation of the bacterial species name and a number. Similarly, there are enzymes that are used to connect fragments, the ligases (Griffiths et al., 2010).

Cloning Genes

All manipulations of genetic engineering require multiple copies of the DNA sequence or gene of interest. The original methods of getting multiple copies relied on bacteriophage or plasmid vectors to introduce the foreign DNA into bacteria to produce these copies, as each modified cell produces multiple copies, and the bacterial culture itself increases. This is done by first physically isolating the vector, opening its DNA with a restriction enzyme, and binding in DNA from the organism being studied that has also been cleaved with a restriction endonuclease. A new population of bacteria is then infected with the altered vector. Given an appropriate way of selecting the population of bacteria so that it uniformly has the DNA of

interest multiplying within, one can isolate a large population of vector molecules with the desired sequence, which is then freed by enzymatic cleavage once again.

Fragments of DNA are identified by physically separating them by electrical charge and molecular weight through gels. The DNA of the vectors and bacteria are generally in the range of 1–10 000 bp, and there are a sufficiently small number so that the fragments can be identified with a simple staining technique, usually a compound that binds to DNA and fluoresces under ultraviolet light. The larger quantity of fragments that would be isolated from more complex organisms produces a smear with such dyes, so the base-pairing property of DNA, the obligate pairing of adenine with cytosine and guanine with cytosine that allows for both recognition and synthesis of the linear sequence, is used to identify the same sequence on the gel by labeling a known fragment with an isotope or fluorescent dye. The labeled molecules are called probes. This is also the basis for identifying genetic variation in organisms, either for basic studies or identification of mutations associated with disease.

Isolation of fragments produced by digestion with several enzymes, used both singly and in combination, allows for the construction of a physical, restriction fragment map. Smaller fragments may be replicated, followed by the chemical analysis of the base sequence within fragments, which are then assembled into the final base sequence of the gene. Once the sequence is known, production of useful amounts of a region of DNA may now be done enzymatically *in vitro* with the polymerase chain reaction. In this technique, the region between two primers, one from each strand of the final DNA molecule is copied in a logarithmic fashion by a heat-resistant DNA polymerase from a small amount of genomic DNA (it has been done with single cells), using multiple heating and cooling cycles. This technique is also used extensively in diagnostic work (Strachan and Read, 2010).

Modifying Cells to Produce Proteins

A number of strategies have been used to produce large amounts of peptide or protein. Multiple techniques have been necessary because of the different kinds of cells that have been used. The production of human insulin, one of the earlier products produced commercially, is a useful model, which is an example of 'expression cloning.' The sequences for the A and B chains were introduced into separate vectors in sequence with a bacterial promoter (a signal to turn a gene on) and the enzyme β-galactosidase that produces colored bacterial colonies. This arrangement is necessary because bacteria will not just produce the human protein if only the structural gene is introduced. The bacteria are tricked into producing a fusion protein: a bacterial β-galactosidase with a human insulin chain sequence at the end. After selecting the colonies by color, mass cultures are produced from which the fusion proteins can be purified. The normal insulin dimer is then produced chemically by removing the β-galactosidase, purifying the chains, combining the chains, and allowing them to refold and form the sulfide bridges between the two chains.

Expression cloning in bacteria works well if the peptide or protein is composed entirely of the amino acid sequence. Many functional proteins contain specific carbohydrate groups at precise locations on the chain that are attached after translation. These modifications are different in different classes of organisms, so techniques using yeast, plant, cultured insect, other mammalian, or human cells have been used to make the complete molecule. Another problem that is addressed in this approach is the elimination of bacterial toxins that cannot be removed from the desired protein product mixture. The engineered DNA can be introduced into these cells by a variety of methods. Physical techniques to get the DNA inside the cell include electroporation that employs a current, bombarding the cells with coated particles such as gold, or calcium salts, or heat. Lipid droplets are also being tried. Artificial yeast chromosomes have been produced to move gene constructs. For the cultured insect cells, modified baculoviruses are used (these are the viruses that have invertebrate hosts). In mammalian systems, several viruses have been used, including retroviruses (the class of agents involved in acquired immunodeficiency and tumor transformation in experimental organisms), adenoviruses (agents that typically produce respiratory disease, however, some strains are capable of producing more severe systemic disease), and herpes simplex.

The goal of expression cloning is to produce large amounts of protein that can be purified more easily and in much larger amounts than is possible using chemical techniques starting with cells from the normal tissue. On the research laboratory scale, the three-dimensional structure of the whole protein or the active region can be determined by a combination of nuclear magnetic resonance and X-ray crystallography. This information is useful for understanding function or designing small molecules that are expected to have pharmacological actions. This is then one element of the strategy in rational drug design. If large quantities of the protein is to be used as a product, the growth of the modified cells has to be done on an industrial scale that is an engineering problem similar to that used in the production of a number of antibiotics (Glick and Pasternak, 2003).

Modifying Organisms

An organism that has been engineered so that it has a gene from another species integrated into its genome is called a 'transgenic organism.' These techniques have been used to produce plants and animals expressing mutated genes of that species to study function, with mutated or genes introduced from another species with desired agronomic properties, as models of human diseases, and to produce therapeutic products. There is a large and continuously growing literature of studies in the mouse.

Two procedures have been widely performed in mice: the interruption of a mouse gene to eliminate its function, for which the term knockout has been used, and introduction of a transgene. The 'standard' procedure employs classical, cellular, and molecular genetic techniques. The gene to be studied is first cloned and then introduced into a targeting vector in such a way that the coding sequence of the gene is interrupted by the neomycin-resistance gene. The vector also has the thymidine kinase gene from herpes. Embryonic stem cells are obtained from a brown mouse and placed in culture. The cells are then exposed to the vector. There are three possible outcomes. The

vector does not insert at all, the whole construct inserts at random in a chromosome, or only the desired coding sequence and the neomycin-resistance gene insert into the normal location on the chromosome. Treating the cells with a neomycin analog and the antiviral agent ganciclovir will kill all the cells except the ones with the integrated sequence. The surviving stem cells are injected into the blastocyst stage embryo of a black mouse and placed in a surrogate mother. If a chimera is formed, it will have a coat of two colors. The chimeras are mated with black mice, and their brown offspring tested for the modified gene. Those that are heterozygous are mated, and one of four will be homozygous for the modification.

In addition to the introduction of genes into stem cells by vectors, injection of the desired sequence has been done by some of the physical methods discussed earlier such as electroporation, coated gold particles, and salt precipitation. Some transgenics have been derived from direct injection of the plasmid into the egg.

A newer experimental system, namely the use of knockdown of functions of genes by the use of morpholinos, i.e., synthetic oligonucleotides, has been used in zebra fish to study the role of mutations identified in human subjects. This system allows manipulation in a vertebrate that is more rapid and economical than a mouse.

The production of genetically identical organisms, cloning in the original sense, was first done in amphibians by nuclear transplantation into fertilized ova from which the original nucleus was removed. This was done widely in mammals by using embryonic cells as the nuclear donor. The production of the sheep named Dolly was noteworthy because the donor nuclei were obtained from adult mammary cells that were maintained in cell culture. This precipitated a round of discussion about the feasibility and the desirability of doing this in human beings. The claim was made that this would be an alternative for infertile couples and therefore acceptable. It is necessary to point out to people who would propagate themselves for narcissistic reasons that the derived individual would not be absolutely the same because of the developmental environment, both before and after birth (Hubbard and Wald, 1997).

Another possible use of this technology that has been proposed is the therapeutic cloning of replacement tissues or organs. Cells would be biopsied from the eventual recipient and placed in culture. Nuclei from these cells would be transplanted into eggs from which the nuclei have been removed; these eggs will be allowed to develop to the blastocyst embryonic stage for the isolation of embryonic stem cells that are treated to produce the desired cell types. This avoids the problem of using fertilized eggs but still involves the use of human eggs and early embryonic stages (Gurdon and Colman, 1999).

Gene Therapy

The goal of gene therapy is to provide a functional protein to an individual whose genotype leads to a disease because the protein is missing or modified so that it is not functional. There are two potential modes. In 'germ line therapy,' the modification would be heritable, and the individual's offspring potentially would not be affected. In 'somatic cell therapy,' only the treated individual would have the modification. There have been many arguments against germ line therapy including our inability to know whether potentially harmful changes in the sequence have been made inadvertently. All the trials to date have been in somatic cells for the treatment of inherited disease and cancer by control of cell death.

Two strategies are being attempted. For those disorders for which bone marrow transplantation has been effective, the gene is introduced into marrow cells, the population of which is then expanded and infused into the patient. The techniques for gene introduction are similar to the ones previously discussed: viral vectors and chemical or physical techniques. An immune deficiency disorder, adenosine deaminase deficiency, was the first attempt reported. Although the modified cells express the enzyme, repeated infusions of treated cells have been necessary, and the patients have continued to receive chemically modified enzyme, so it is not clear whether or not gene therapy alone is sufficient.

Other trials have used viral vectors to treat target organs, such as the lung in cystic fibrosis. The therapeutic trail of an adenovirus-mediated transfer of a gene to the liver has received general media attention because of the death of a participant. Evidently, other participants in gene therapy trials have died, although it is not clear how many of those deaths are a result of the procedure (Strachan and Read, 2010). Currently, there continue to be trials for immunodeficiency diseases, β-thalassemia, hemophilia, several forms of leukodystrophy, and retinal dystrophy.

Applications to Behavior

The application of these techniques in behavior is loaded with scientific, ethical, and legal complications. Part of the problem stems from the very human desire to have a simple answer to a complex problem. Genetic, environmental, and developmental factors interact to produce behavior, and it is difficult to distinguish the role of each component. One should ask if it is even desirable to do this because of the mixture of potential benefit and risk. It is clear that each behavioral trait is heterogeneous. Mutations of a single major gene resulting in deficiency of adenylosuccinase produces an autistic phenotype. For this class of disorder, a particular drug, expressed protein, or even gene therapy could work, but in the more usual instance of several genes and environmental factors, it is unlikely that such a unitary approach would be effective. The promise of a solution to disease problems by definition of molecular mechanisms has been difficult to achieve. We still do not have an answer in the case of sickle-cell anemia, the first disorder to be described in this manner. Common behavioral traits would be more difficult because of the nature of gene–-gene interactions as well as gene–environment interactions.

The example in the previous paragraph employed both standard pedigree analysis as well as biochemical techniques. The expansion of technology in the last few years has given new methods of genetic analysis and a new insight into human genetic variability, as well as possible explanations of mental disorders. The first technique is the chromosomal microarray that identifies changes from the standard, diploid copy number in regions of the genome. From cytogenetic analysis, such

changes had been associated with disorders that include mental retardation as part of the condition. Both additions, i.e., duplications, and subtractions, i.e., deletions, had been described. The array allows discovery of much smaller duplications and deletions. The smaller of these are often harmless, inherited traits. Several of these have been associated in multiple studies with autism spectrum disorder and schizophrenia. These genetic changes as yet only account for a minority of the affected individuals (Smith, 2011).

The new sequencing technology expands on the observations in the previous paragraph. This has allowed more identification of mutations of single, Mendelian genes as well as the existence of very complex chromosomal rearrangements (Talkowski et al., 2012). A pattern of new, detrimental mutations of genes involved with the development and maintenance of synapses is emerging in individuals with developmental issues and autism (Neale et al., 2012).

The technology therefore will create the possibility of diagnostic tests for the presence of variants at these genetic loci that might be involved in diagnostic confirmation, or even asymptomatic screening without necessarily having the ability to safely and ethically treat those in whom the genetic variant is identified. Furthermore, since it is well known that the genotype does not always predict the phenotype even for such things as emphysema associated with a variant α-1-antitrypsin, one should question this approach with respect to behavioral characteristics (Hubbard and Wald, 1997).

The second group to consider is the collection of positive and negative personality or behavioral traits that have been considered by educators and others interested in social welfare. This list of characteristics has included aggressiveness, criminality, laziness, or on the other side of the spectrum, altruism. This author is not aware of any studies that clearly show inheritance in a Mendelian pattern. The clustering in families may be biologic in part, but there are many social and environmental influences in these behaviors. A good explanation for part of the variability is cultural transmission, or learning (Creanza et al., 2012). Using genetic information to design pharmacologically active agents is being used for drugs interacting with receptors influencing neural function. A similar problem arises here. Will the intervention be beneficial to someone who is suffering or will it be used to control individuals who are designated by those in authority to be deviant? Modifying the environment to enhance development is effective and poses less of a biological risk than drugs or gene therapy (Duyme et al., 1999). The relative economic costs are unknown, but the human ramifications are immense.

Abstract

Organizational psychology has increasingly integrated perspectives and findings from genetic approaches. In this article, we provide an overview of genetics-based investigations on variables of interest to organizations, such as attitudes, personality, and affectivity. We also discuss synthesizing perspectives and boundary conditions for genetic effects. Finally, we discuss ethical and legal issues surrounding genetic research in organizations, and suggest possible avenues for future research.

Introduction

Organizational research has been increasingly interested in the role of genetics in influencing the ways individuals think, feel, and behave. Over the past three decades, this program of research has become increasingly nuanced, detailed, and programmatic. Without doubt, these investigations have provided valuable insights on how genetic factors shape organizational outcomes of interest such as job satisfaction (Arvey et al., 1989), job choice (McCall et al., 1997), and leadership role occupancy (Arvey et al., 2007; Ilies et al., 2004). These developments are not limited to examinations of outcomes – other approaches have provided insights into antecedents and processes, ranging from personality dispositions (Ilies and Judge, 2003) to task persistence (McCartney and Berry, 2005) and information processing (Caldu and Dreher, 2007). This body of work has provided valuable insights, broadened our knowledge, and honed our predictive ability.

The success of these efforts is perhaps not surprising, as "individual differences in virtually all domains have a genetic component" (Ilies et al., 2006). Indeed, models that have integrated previously established personality and affectivity perspectives with genetic or heritable arguments and evidence (e.g., see Ilies and Judge, 2003) have demonstrated the importance of these factors for a variety of approaches that utilize individual differences as predictors or boundary conditions in the effects of interest. That is, because most traits, whose importance is established in the organizational literature have a genetic component, these components and mechanisms become a valuable tool of inquiry that helps us understand the ways people feel, think, and behave in (as well as feel, think, and behave in response to) their environments.

Apart from their important role in advancing the accumulation of knowledge and scientific consensus, these efforts further provide important theoretical and practical contributions. By enhancing the organizational literature with a theoretical background based on biological mechanisms, they set differences such as the personality/situation or nature/nurture debates in an arena where they can be more closely examined empirically, allowing us to do so with a better understanding of the variance to be explained and the processes behind such explanations (Ilies and Judge, 2003). Relevant to organizations, such an approach allows us to examine a variety of factors relevant to between-people as well as dynamic models of employee functioning, and potentially design better ways to intervene.

This article thus seeks to contribute to these efforts in general by providing an overview and synthesis of such research, adding to and supplementing prior synthesizing work in this area (see Ilies and Judge, 2003; Ilies and Dimotakis, in press; Song et al., in press). Furthermore, we aim to identify fruitful areas of future research, and provide suggestions for further integration. Finally, we discuss ethical and legal implications that integrating genetic factors into organizational research can have.

We begin with an overview of the literature, which we will generally summarize under a history of research on individual differences (including personality, cognition, and affectivity) as well as attitudes and behaviors. We then progress into a discussion of studies integrating individual differences with organizational outcomes, and discuss more recent and nuanced approaches to these areas of inquiry. Finally, we present an overview of recent issues of legal and ethical concern that are becoming increasingly relevant for all fields that border the genetic field. In each section, we will generally group the literature under organizationally important antecedents, processes, or outcomes, according to commonly utilized models in the field.

Overview of Genetic Research

Organizational research on genetic factors attempts to understand and explain where variation in individual variance in traits of interest arises; it seeks to establish the role of the environment and genetics in influencing a variety of individual factors. In the organizational research realm, such work aims to uncover the role of individual genotypes in a host of factors that matter. Such factors include individual differences (such as personality and cognitive ability), attitudes (such as job satisfaction), and behaviors (such as performance or leadership).

At its most basic form, this line of research aims to partition the variance in some construct into genetic and environmental components. For example, when examining a specific attitude, research has aimed to uncover the proportion of variance in this attitude that can be accounted for by genetic differences, with one such estimate being the parameter of heritability (Ilies et al., 2006; McGue and Bouchard, 1998). These influences can

be further decomposed. Genetic influences on attitudes, personality, or other traits can be separated into additive genetic effects (transmissible across generations) and *nonadditive genetic effects* (not transmissible). The effects of environmental variation on individual traits can also be further decomposed into those associated with *shared environments* (e.g., common experiences that individuals might have been exposed to by, for example, being raised in similar environments), and into these effects associated with *unshared environments* (i.e., environmental influences that are unique for each individual).

The proportion of variance in a trait accounted for by the influences described above can be estimated by examining similarities and differences among twins. In the simplest version, examining the correlation in a trait among monozygotic twin pairs that were raised apart will provide an initial estimate of genetic influences; as these twins are genetically identical, but were exposed to different circumstances growing up, any similarities between them must be largely attributable to genetic factors.

More sophisticated models utilize latent factors to compare the covariance in the traits of interest among four types of twin pairs; monozygotic twins raised together, monozygotic twins raised apart, dizygotic twins raised together, and dizygotic twins raised apart. This allows for the partitioning of variance in the variables of interest into additive genetic variance, shared environmental variance, and nonshared environmental variance (see Ilies and Judge, 2003). These models are then compared with alternatives to compare fit, and the best fitting approaches are used to estimate variance components. Recently, more sophisticated models are beginning to emerge that utilize multiple groups of related and nonrelated individuals to better examine the variance attributable to shared and nonshared factors – these models are showing great promise (see Hahn et al., 2013, for an example of this approach).

Furthermore, other efforts focus on the molecular level by examining the associations of distinct markers with personality, attitudinal or behavioral phenotypes. This approach involves directly examining the effects of the presence of a specific allele on the variable of interest instead of examining the effects of genetic factors overall (see Plomin et al., 2008, for an overview; Song et al., 2011, for an example of this approach). Finally, as with other analytic approaches, estimates from all of the above approaches can be further subjected to moderation and mediation analyses to either examine boundary conditions for genetic influences (or lack thereof), and to examine possible mediating variables in the causal chain (as we will discuss below).

Individual Differences in Personality, Cognition, and Affectivity

We begin our review of genetic factors in organizational research with an overview of individual differences, which include personality, cognitive ability, and affectivity. This is because these factors are commonly held to represent core antecedents of important organizational processes and outcomes, and as such, represent important starting points or foundations for subsequent research (see Ilies and Judge, 2003; Plomin, 1999). Even though their influence is by no means restricted to (or even mostly represented in) organizationally focused research, these factors remain central to models of workplace functioning.

In terms of personality, studies have been generally supportive of the importance of genetic influences in a variety of frameworks. For example, the personality dimensions included in the Big Five personality factors (see Goldberg, 1990) have been found to have mean narrow and broad heritability estimates of 0.34 and 0.45, respectively (Loehlin, 1992). Similar results, with an average heritability estimate of 0.41, were reported by Bouchard (1994) in an analysis of the Minnesota Study of Twins Reared Apart dataset. In terms of specific estimates, Jang et al. (1996) reported broad genetic influences of 41, 53, 61, 41, and 44% for Neuroticism, Extraversion, Openness, Agreeableness, and Conscientiousness, respectively, utilizing a sample of 123 identical and 127 fraternal twins. These authors also reported significant estimates of personality facet heritability, although they did note that the latter showed significant influence of nonadditive traits. Similar genetic effects have been used when utilizing other personality frameworks, such as the Honesty and Humility (H) – Emotionality (E) – Extraversion (X) – Agreeableness (A) – Conscientiousness (C) – Openness to Experience (O) (HEXACO) model (see Veselka et al., 2010).

Cognitive ability has also been found to have a significant heritable component (Plomin, 1999). In a study utilizing the Minnesota Study of Twins Reared Apart, Bouchard et al. (1990) reported that 70% of the variance in cognitive ability could be attributed to genetic factors, while McClearn et al. (1997) report similar findings (62%) in an older sample of Swedish twins. However, such effects are not necessarily stable or universal. Haworth et al. (2009) report that the heritability of cognitive ability increases as people age, from 41% in childhood to 66% in young adulthood; such change is expected to persist or increase further with increasing age. Finkel et al. (1995) comparing twins from the Minnesota and Sweden samples found that estimates of heritability diverge in late adulthood between the samples. Turkheimer et al. (2003), on the other hand, report that socioeconomic status can affect heritability estimates in young children, with the vast majority of differences being accounted for not by environmental effects in impoverished families, but by genetic effects in affluent ones.

Finally, research has also examined the genetic component of affectivity, or the predisposition to experience positive and negative emotional states. The most commonly used framework in such examinations centers around Positive and Negative Affect (see Watson, 2000). Positive affect centers on feelings such as pride and happiness, while negative affect reflects anxiety and anger (Watson et al., 1999). These two factors have reflections in both personality (with extraversion corresponding to positive and neuroticism corresponding to negative affect; see Watson, 2000) as well as regulatory biobehavioral systems, with positive affect being reflected in the behavioral approach system and negative affect being reflected in the behavioral inhibition system (see Fowles, 1987; Gray, 1990; Watson et al., 1999). Research has demonstrated the importance of genetics for both the affectivity dimension as well as their associated factors. For example, Finkel and McGue

(1997) found that positive and negative emotionality have heritability estimates of 0.50 and 0.44, respectively, while Bouchard and McGue (2003) reported similar results (0.43 and 0.47). Furthermore, genetics can play a role in how affective experience varies across situations – that is, genetic factors are not only important for how individuals feel in general, but also for how they react affectively to different contexts. For example, Riemann et al. (1998) found that twin pairs exhibited similarities in affective experiences across different situations, in addition to the expected overall affective dispositions.

Attitudes and Values

Attitudes have long been represented in genetic and organizational research. In fact, attitudes such as job satisfaction represented the initial focus of research bridging these two areas. One of the first such studies was a report of significant intraclass correlations for general and intrinsic job satisfaction among monozygotic twins raised apart (Arvey et al., 1989). This work provided an initial indication of the importance of genetic factors in explaining workplace attitudes. Expanding on these findings, Arvey et al. (1994) reported that in two studies, utilizing samples from the Minnesota Twin Family Registry and the National Academy of Sciences and National Research Council twin sample, genetic factors accounted for significant variance in overall job satisfaction.

Job satisfaction studies have not always shown a genetic effect, however. Utilizing a sample of more than 500 monozygotic and dizygotic twins raised together and apart from the Swedish Adoption/Twin Study of Aging, Hershberger et al. (1994) reported no significant genetic influences on job satisfaction, although they did report significant genetic effects on other workplace-related attitudes and perceptions. Their item was, however composed of a one-item measure, meaning that unreliability could explain this lack of significance.

Naturally, research on attitudes has not been limited to job satisfaction. Tellegen et al. (1988) reported a heritability estimate of 48% for general subjective well-being, while Harris et al. (1992), utilizing a sample from Swedish Adoption/Twin Study of Aging, found that 32% of the variation in life satisfaction scores was attributable to genetic factors. In a later investigation, Stubbe et al. (2005) reported that nonadditive genetic factors explained 38% of the variance in life satisfaction. Additional evidence for the importance of genetic effects in explaining life satisfaction was provided by Johnson and Krueger (2006), using a sample of 719 twin pairs from the National Survey of Midlife Development, who found that genetic effects accounted for a substantial amount of variance in individual levels of life satisfaction. Furthermore, these authors found that these effects were moderated by level of financial position and perceived control, with genetic effects being stronger at higher levels of these factors. In a more recent effort, Hahn et al. (2013) found that a third of variance in life satisfaction was attributable to genetic effects, and further noted that shared environment effects were more pronounced for nontwins compared with twins.

In general, genetic effects can account for a wide variety of attitudes and beliefs. Keller et al. (1992) and Arvey at al. (1994) found that genetic effects accounted for a variety of workplace needs and values, although genetic effects varied in importance across values and needs. In a recent study, Weber et al. (2011) reported that genetic effects could also account for variance in group identification. Drawing from 691 twins from the National Survey of Midlife Development in the United States, these researchers found that genetic effects accounted for 41, 36, and 19% of racial, ethnic, and religious identification, respectively. Relationships have also been reported between genetics and other attitudes, such as conservatism (see Bergen et al., 2007).

Behaviors and Performance

An important body of work is also concerned with how genetics influence how people behave as well as how these factors ultimately affect performance in the workplace. Such work has focused on topics ranging from specific facets of workplace behavior, such as turnover or leadership role occupancy, to more general factors such as performance, discretionary behavior, and motivation.

As with attitudes, research has generally been supportive of the importance of genetic effects in this area. In terms of turnover across both occupations as well as specific jobs, McCall et al. (1997), utilizing a sample of 1236 monozygotic and 1165 dizygotic twin pairs, found that 36% of job change frequency and 26% in occupation change frequency could be attributed to genetic factors.

More specific classes of behavior have also been found to have a genetic component. In a study involving 1285 monozygotic and 849 pairs of dizygotic pairs of twins, Zhang et al. (2009) found significant heritability estimates for entrepreneurial behavior (although these effects were limited to the females in the sample). In a related study, Nicolaou et al. (2009) reported that a significant part of the variance in opportunity recognition (an important component of entrepreneurial behavior) could be attributed to genetic factors.

Similar results have been found in investigations of leadership role occupancy in general as well as in investigations of specific leadership behaviors. Li et al. (2012), utilizing a sample of 196 sets of twins, showed that genetic influences accounted for 48% of the variance in transformational leadership behaviors and for 30% of the variance in leadership role occupancy. More targeted investigations have also borne fruit; De Neve et al. (2013) found that a quarter of the variance in leadership role occupancy can be accounted for differences in a specific genotype; individuals with two A alleles of rs4950 were found to be more likely to have leadership positions compared with those with one or two G alleles in rs4950.

Genetic effects have also been found to relate to a variety of performance-related factors (although direct investigations of the role of genetics in job performance represent an underdeveloped area). In a recent investigation, Gottschling et al. (2012) found that, in a sample of 280 twin sets in Germany, genetic factors accounted for significant variance in a variety of scholastic achievement factors. Similarly, Deater-Deckard et al. (2005), in a sample of 92 monozygotic and 139 dizygotic pairs of twin children, found a significant heritability estimate for task persistence (0.59), which

furthermore tended to increase over time; these findings represent evidence for the role of genetics in the motivational predictors of performance.

More direct evidence can be perhaps found by looking at the undesirable components of contextual behaviors, such as aggression and altruism. In an initial study of 573 twin pairs from the University of London Institute of Psychiatry Volunteer Twin Register, Rushton et al. (1986) found significant genetic components for altruistic and aggressive tendencies (with genetic effects accounting for about 50% of the variance in this sample). The aggression findings were further supported by Bergen et al. (2007), who found a significant genetic effect for this class of behaviors. Specifically, externalizing behaviors were found to have a significant heritable component, and this was found to increase over time; this increase corresponds well with an established pattern of strengthening of genetic effects across the lifespan found in previous research. Rushton (2003), on the other hand, found additional evidence for a heritable component of prosocial tendencies (similar to altruism).

Mediating the Effects of Genetic Factors

The research efforts described above have provided important insights into the importance of genetic effects for organizational factors. However, examining organizational outcomes or their antecedents in isolation provides fairly limited contributions; approaches that synthesize genetic effects with established theoretical outcomes were needed, a fact that was actually identified fairly early in this literature. For example, the mediating role of personality in explaining the linkage between genetic effects and job satisfaction has been long hypothesized and expected (see Arvey et al., 1989). As a result, recent efforts have focused on providing more comprehensive models, providing linkages from genetics to attitudes and behaviors through individual differences in personality, cognitive ability, and affectivity. These approaches provide important contributions in demonstrating how genetic effects operate, and in linking this literature to broader organizational research, both informing and advancing the field.

In general, mediated models integrating genetic effects with organizational research either focus on how a dispositional factor can explain genetic influences in an outcome of interest or on how genetic effects can explain a relationship between two associated factors. While often mathematically similar, these two approaches represent different conceptualizations and investigate different parts of the causal chain. Both can provide important insights, and generate interesting questions for future research.

The former approach generally links individual differences in personality or affectivity to attitudes, values, and judgments, and ultimately to behavior in the workplace. Personality and affectivity are thus considered the mediators of genetic effects or, alternatively, the first part of a causal chain that considers how individual differences result in differences in perception or cognition, and ultimately behavior.

In terms of dispositional mediators, research efforts that examine how personality variables mediate the effects of genetic factors have provided important insights on the causal chain represented by these factors. This is not surprising, as personality factors have long been considered central to a number of models of workplace functioning (see Ones et al., 2007), as well as having recognized genetic components themselves (see Bouchard, 1994; Loehlin, 1992). In other words, researchers have expected and found that genetic factors are associated with workplace outcomes because of their association with individual differences.

In an initial synthetic investigation of the mediating role of personality and affective dispositions, utilizing extant meta-analyses and previously established heritability estimates, Ilies and Judge (2003) found that approximately 45% of the genetic influences on job satisfaction were mediated by positive and negative affectivity, while around 24% were mediated by the Big Five factors of personality. Similarly, in a study of 594 Swedish twins, Judge et al. (2012) reported that core self-evaluations accounted for almost half the effects of genetic factors on experienced work stress. In terms of other negative factors, Kendler and Myers (2010), in a sample of 542 same-sex twins, found that personality accounted for a significant amount of the relationship between genetic factors and depression (with the driving traits being neuroticism and, to a lesser extent, conscientiousness). Maas and Spinath (2012) found that personality factors explained part of the genetic effects on work engagement and resistance to stress (although the authors noted that the magnitude of these effects was lower than expected).

More general investigations of attitudes have provided results in line with the above. Olson, Vernon, Harris, and Lang, in a study involving 195 pairs of monozygotic and 141 pairs of dizygotic twins, found that personality factors (especially sociability) had an important mediating role in the relationship between genetic factors and a variety of general attitude factors (including such things such as gender differences, leadership importance, and intellectual pursuits).

Personality factors have been also found to mediate the effects of genetic factors on behavior. For example, Shane et al. (2010), utilizing a sample of 3412 monozygotic twins from The United Kingdom and 1300 monozygotic twins from the United States, found that openness to experience and extraversion were associated with entrepreneurial tendencies, a general class of work behaviors. Similarly, Zhang et al. (2009) found that personality (specifically, extraversion and neuroticism) accounted for a significant part of the relationship between genetic factors and entrepreneurial behaviors in the female component of their sample.

Genetic Factors as Mediators

It should be noted, however, that not all research has followed mediating approaches similar to the ones above. Instead of focusing on explaining what traits might mediate the effects of genetics on other individual factors, researchers have aimed to uncover whether an association between two traits are due to common genetic factors (as well as shared environments). For example, Bergeman et al. (1991) investigated the mediating effect of genetic influences on the relationship between perceived adequately of social support and a number of subjective well-being indicators in a sample of 424 older twin

pairs. Indeed, these authors reported that a substantial amount of the social support – well-being relationship was accounted for by genetic effects (56–65%).

Similarly, Nicolaou et al. (2009) reported that genetic factors accounted for a large percentage (53%) of the relationship between recognizing opportunities and the tendency to be an entrepreneur, while Li et al. (2012) found that genetic factors accounted for 78% of the correlation between transformational leadership and leadership role occupancy estimated in their sample. These results indicate that alternative conceptualizations of genetic influences in the causal structure linking attitudes and behaviors can also be supported by data, and highlight the importance of investigating these phenomena from a variety of viewpoints.

Other approaches have focused on the commonalities between traits or constructs. Veselka et al. (2010) found that the relationship between the HEXACO factors of personality and trait emotional intelligence can be fully attributed to common genetic and shared environmental factors. In an interesting application of this framework to a construct validation approach, Moore et al. (2010) found that genetic factors accounted fully for the demonstrated correlation between a verbal and a nonverbal measure of the Big Five. On the other hand, Kandler et al. (2012) utilized a multitrait – multimethod approach with a twin sample to show the areas of similarity and difference between temperament and personality frameworks.

Boundary Conditions

We have previously mentioned the results of Johnson and Krueger, who found that financial and perceptual factors moderated the importance of genetic effects for life satisfaction, as well as the findings of Turkheimer et al. (2003), related on the moderating effects of poverty on the relationship between genetics and cognitive ability. Other boundary conditions might reside with the factors under consideration. Conway et al. (2011) found that attitudes that are more complex demonstrated higher heritability estimates, even when controlling for a number of associated factors.

Genetic factors have also been hypothesized to influence the ways in which genetically derived traits can operate. For example, Tesser (1993) argued that attitudes with a stronger heritable component should be more readily accessible and harder to change. Indeed, Tesser et al. (1998) reported that attitudes that are more heritable were associated with greater availability of physiological responses, and were more resilient.

Directions for Future Research

A number of findings reported above hint at potentially fruitful areas of future research. Utilizing genetic factors as a biological cornerstone on which to base nomological networks of personality, affectivity, and temperament has provided important insights already, and can be expected to contribute to a variety of between-person models of workplace functioning and behaviors. The report of Kandler et al. (2011) of congruence and divergence between personality and temperament frameworks can represent an initial example of such efforts.

Other issues such as the similarities in jobs held by monozygotic twin pairs points at the importance of examining individual situation and context seeking, providing another avenue for how genetic effects can operate, generating future directions from literature ranging from turnover to job crafting research. More generally, investigating the reasons why genetic factors might predispose individuals to seek (or avoid) specific contexts, and the contextual factors that might stimulate or drive such decisions, could also be interesting.

Methodological advances both in terms of data analysis as well as available datasets will surely aid these and other efforts. Such advances can include increased capabilities to examine environment–gene interactions, and modeling trait transmission from parents to children (see Zyphur et al., 2013, for an example). Additionally, the increasing use of multilevel structural equation modeling can further refine estimations of genetic influence, and more accurately portray complex and comprehensive mediated models to test causal pathways between genetics, individual differences, and organizational outcomes of interest.

Legal and Ethical Issues

As scholarly understanding of genetic effects increased, policy makers were increasingly concerned with the potential implications of such advances for employers and employees. This interest has resulted in emergence of legislation both at the national (such as the Genetic Information Nondiscrimination Act (GINA) of 2008 in the US) and transnational levels (such as the European Union (EU) Charter of Fundamental Rights, and the 1997 United Nations Educational, Scientific, and Cultural Organization (UNESCO) Universal Declaration on the Human Genome and Human Rights).

Overall, we expect that advancement in research on genetic factors in the workplace, as well as advances in genetic testing in general, will be found to both have the potential for high levels of utility as well as abuse, on the part of employees as well as employers. Future legal discussion will be had on the rights of employees to safeguard privacy and secure against discrimination, and these discussions will likely become more pressing as screening technology and knowledge concerning genetics and individual workplace outcomes becomes more substantial.

Conclusion

The research coming out of the field of genetics has produced important, relevant findings for organizational studies. Researchers now understand the genetic components of core areas and central factors of the field, including personality, attitudes, and behavior. With increased growth in this area of research, in addition to an emphasis on multidisciplinary approaches to the social sciences, we expect there to be more opportunities in the future to integrate genetic factors into the organizational psychology literature and associated fields.

Abstract

Genetic screening aims to (1) ensure health gain by providing opportunities for disease prevention and treatment, or (2) increase reproductive choice. Genetic screening can be done at different stages in life such as preconception, prenatal, neonatal, and later in life. The advances in genetics research and technology have made screening for an increasing number of medical disorders possible. Genome-scale tests are expected to change the screening landscape even further. Before introducing these new screening initiatives, it is essential to weigh the benefits against the harms of screening, including addressing the ethical, economic, and societal issues.

Introduction

Definition

Genetic screening involves the medical examination of individuals for the early detection or exclusion of a hereditary disease or a genetic predisposition to a disease, or to determine whether a person carries a predisposition that may produce a hereditary disease in their offspring (Godard et al., 2003). A distinguishing feature of screening is that a test is offered without being requested. Typically, a country's health care system will take the initiative. Genetic screening is considered an activity of community genetics – the application of medical genetics for the benefit of large numbers of people. Screening can be offered systematically in the form of large-scale programs, aimed either at a whole population of asymptomatic individuals (universal) or at people in a predefined target group (selective), such as neonates or pregnant women. Early-detection screening means that testing is applied to those who have not (yet) sought medical aid as a result of physical signs, symptoms, or anxiety. Screening can also entail people responding to an advertisement (or a website offer) for a health check at a clinic or health organization (Health Council of the Netherlands, 2008) or direct-to-consumer (DTC) genetic testing (Borry et al., 2011). DTC genetic testing typically involves collecting a sample at home, mailing it back to the laboratory, and subsequently receiving results without having to consult a health care professional.

Characteristics of Genetic Screening

The main differences between diagnostic genetic testing and genetic screening are shown in Table 1. An important difference is that genetic diagnosis is often indicated or requested by those who have an a priori increased risk, for example patients who have symptoms of a disease, family members of patients already diagnosed, or prospective parents with a known increased risk of having an affected child. Genetic screening, in contrast, may be seen as being imposed on persons (Godard et al., 2003). Moreover, as will be explained in this article, in diagnostic testing results are usually definitive, whereas in screening results are sometimes preliminary.

Testing is not restricted to the analysis of DNA, but includes the use of any test (molecular, cytogenetic, biochemical, or imaging) that yields genetic data that are designed to detect and exclude hereditary disease, genetic predisposition to disease, or carrier state. One can thus test on a genotypic level (e.g., DNA, RNA, gene, and chromosome) or a phenotypic level (e.g., appearance and characteristics), or look at metabolites (e.g., proteins and enzymes). Screening for genetic risk can also be done by taking a family history (Burke et al., 2011). As with other types of medical screening, diagnostic confirmation of a positive screening test is an integral part of the screening procedure. For example, screening for Down syndrome during a woman's pregnancy can be done using a combined test consisting of an ultrasound examination to measure the nuchal translucency of the fetus (phenotypic level), and a blood test to check for levels of certain proteins and hormones of the mother. When combining these data with the mother's age, the chance of a child with Down syndrome can be determined. If the chance is higher than average, an invasive diagnostic test is offered by means of chorionic villus sampling or amniocentesis for definite diagnosis.

The difference between genetic screening and other types of screening is that with most forms of genetic screening, one test

Table 1 Differences between a (genetic) diagnostic test and screening test

	Diagnostic test	*Screening test*
Target	Individuals	(Part of) the population
Target characteristics	Persons often worried because of disease symptoms or relatives affected	Persons with no known signs or symptoms
Motive to test	On request or indication	Offer unasked for
Test results	Usually definitive	Sometimes preliminary
Expense and effort	May cost a lot of time, effort, and/or money	Should be cheap and easily applied
Example	Testing for hereditary breast cancer in the family	Blood spot screening in newborns

during a person's lifetime is enough – for example, when screening for a gene mutation that causes disease (e.g., familial hypercholesterolemia). The stability of the genetic characteristics also makes it possible to predict disease long before it would become manifest, thereby making early intervention possible. In contrast, in screening for infectious diseases or cancer, the majority of participants have to return for subsequent testing after a set time period. Genetic screening is also distinguished from other forms of screening because a positive test result may have consequences for family members. This does not apply to all types of genetic screening, however. For instance, finding a fetus with a nonhereditary trisomy 21 Down syndrome (the most common) does not increase the risk for sisters of the pregnant woman, since this is a spontaneous mutation. But when screening shows that someone carries, for example, two mutations of the gene involved in hemochromatosis, this puts his or her siblings immediately at a 25% risk of having the same mutations (Worwood, 2000). They may be grateful to be informed about this since manifestations of this iron overload disease can be prevented effectively by regular bleeding, but the point here is that an individual's decision to participate in a genetic-screening program is to some extent a decision that affects family members who might have preferred to make other choices.

A further characteristic of genetic screening that differentiates it from other types of medical screening is that it does not necessarily lead to the prevention or treatment of diseases.

Aim of Genetic Screening

The aim of genetic screening is twofold: (1) to minimize morbidity and mortality by providing opportunities for prevention and treatment through early detection and initiation of treatment, preferably even before symptoms are evident (e.g., neonatal screening) or by offering risk-reducing preventative measures (e.g., familial hypercholesterolemia); or (2) to increase reproductive choice and family planning (e.g., embryo selection and prenatal diagnosis).

The purpose of screening is thus not just the outcome of the test (e.g., early disease detection) but also ensuing health gain or other benefits to the person and population being tested (Health Council of the Netherlands, 2008). This is often referred to as 'clinical utility' (Grosse et al., 2010).

Types of Screening

Screening at Different Stages of Life

The timing of genetic screening can vary. The earliest possibility for genetic screening is preimplantation genetic screening (PGS) in the case of *in vitro* fertilization (IVF). Preimplantation genetic diagnosis (PGD) is performed when one is looking for a disorder for which this particular embryo has a particularly high risk, while in PGS the embryo in question does not have a much higher risk than other preimplantation or IVF embryos. PGS for chromosomal anomalies, for instance, is done to select embryos with the highest chance of survival.

Screening during pregnancy is a form of reproductive screening to allow for the possibility of prenatal diagnostics and selective termination of pregnancy, to prepare parents (psychologically, financially, etc.) for an affected child, or to timely facilitate medical care before or after birth. Prenatal screening includes prenatal aneuploidy screening (e.g., Down syndrome (trisomy 21), Edwards syndrome (trisomy 18), and Patau syndrome (trisomy 13)) and screening using an ultrasound for other structural fetal anomalies (e.g., neural tube defects or congenital heart disease).

Population-based reproductive carrier screening for autosomal recessive disorders such as cystic fibrosis, sickle cell anemia, thalassemia, and Tay–Sachs disease can be offered to individuals, but because being a carrier is significant only when the partner is also a carrier, it is logical to delay screening for carrier status until a partner has been found and reproductive issues arise. In this case, the couple rather than the individual would be the target. When both partners of a couple are carriers of the same disease, their children are at 1-in-4 risk for the disorder. Since carrier couple screening can be performed premaritally, preconceptionally, or prenatally, it is important to define the best moment for screening within the lifetime of the individual or couple. Premarital screening is seen in cultures where selection of marriage partners is done by third parties, without involving the partners at all. For example, to avoid marriage between carriers of the same disorder, Dor Yeshorim – an international anonymous carrier-screening program that primarily serves the Orthodox Jewish community – has elaborated a carrier-matching program for genetic diseases that are prevalent in the Ashkenazi Jewish population (Raz and Vizner, 2008). Premarital screening after the partners have matched (or been matched) has been normal practice in countries where consanguinity is high, such as Cyprus and Saudi Arabia, and may infringe personal autonomy if provided on a compulsory basis (Wertz et al., 2003).

Preconception carrier screening enables most reproductive options, including not only prenatal diagnosis but also the choices of using PGD, using donor sperm or oocytes, seeking adoption, or refraining from having children. Preconceptional screening is characterized by difficulties in gaining access to the target group in time. The majority of couple-screening programs therefore target pregnant women (and their partners), which has the disadvantage that limited reproductive options are available and decisions may have to be made under time pressure. Some people advocate carrier screening in secondary school, but the time interval between knowing the test results and using the information is long. Carrier-screening programs for X-linked disorders such as fragile X syndrome are offered to women either before or during pregnancy to detect their carrier status. Half of the male offspring of a carrier mother will typically be affected by the disorder, and a carrier daughter may or may not show symptoms (depending on the disease and/or mutation).

Screening of newborns typically aims to identify children with autosomal recessive disease to offer timely intervention to improve health outcome. Examples include a diet restricting phenylalanine to prevent severe cognitive impairment in phenylketonuria (PKU), or nutritional and respiratory interventions to prevent malnourishment and poor growth in cystic fibrosis. High-throughput tandem mass spectrometry makes it possible to screen newborns for many rare inborn errors of metabolism, and in most high-income countries the number of disorders included in neonatal screening is increasing (Javaher

et al., 2010). Proposed testing for untreatable disorders, such as fragile X syndrome or Duchenne muscular dystrophy, is the subject of ongoing debate. The aims of screening, then, are to enable reproductive choice for future children and save parents an often long, diagnostic quest, rather than the early detection to morbidity.

The final stage of screening during life is screening in adulthood (later in life), for example for familial hypercholesterolemia, an autosomal dominant disorder characterized by an increased risk of developing premature cardiovascular disease (CVD) caused by severe elevations in total cholesterol and low-density lipoprotein cholesterol. CVD risk can be reduced by cholesterol-lowering medication (statins) and the adoption of a healthy lifestyle (healthy diet, sufficient physical activity, and refraining from smoking) (Civeira, 2004).

Family-Based or Cascade Screening

Cascade screening is a special type of genetic screening targeted at relatives of identified carriers. Starting from an individual with the characteristic of interest (the proband), one actively offers screening to his or her first-degree relatives. Once the relatives with the same characteristic have been identified, their first-degree relatives are also offered screening, and so on. This type of screening is particularly suitable for dominant disorders, such as familial hypercholesterolemia, and for X-linked disorders with high penetrance (the frequency of cases in which a particular genotype comes to expression) and low mutation rate. It has also been proposed for the detection of couples who are carriers of an autosomal recessive disease such as cystic fibrosis. The disadvantage here is, however, that only a small proportion of at-risk couples can be identified in this way (Morris et al., 2004). In that case, population-based (mass) screening only, or in combination with cascade screening, is a better option. Considerably higher efficiency rates for cascade screening are, however, seen when screening is performed to detect homozygotes for frequent recessive mutations with reduced penetrance, such as hereditary hemochromatosis (Krawczak et al., 2001).

Genetic-Screening Criteria

There are many genetic, medically relevant characteristics for which, in theory, screening could be initiated. It is quite clear that it is not desirable to screen for all these characteristics, and careful selection is needed. In addition to potential benefits, potential harm should also be considered. Harm could be physical, psychological, social, or otherwise, and it is important to take not only the effects of screening on the participants into account, but also the effects on those who decide not to participate. Since the classic Wilson and Jungner screening criteria, developed in 1968 (Wilson and Jungner, 1968), screening criteria have been further refined and adapted to meet requirements for genetic screening (Godard et al., 2003; Nuffield Council on Bioethics, 1993). Some countries have also developed specific legislation.

To assist policy makers in their decisions to develop, implement, or continue a genetic-screening program, guidance is – with further refinements – built on the foundation of the Wilson and Jungner criteria. It is widely recognized that every individual screening program should be pilot-tested first to study the advantages and disadvantages arising from the screening, and to see if it meets the appropriate standards. An acceptable and reliable test should be available with known sensitivity, specificity, and predictive value. Practical courses of action should be available for the participants, such as preventive measures or reproductive choices. The psychological and social effects should be known for the participants and nonparticipants in general, and – in particular – for those among the participants who are faced with a positive test and those among the nonparticipants who are confronted with the disease in themselves or in a child. Participation in the screening program should be voluntary and based on good-quality information and informed consent, and an autonomous decision should be guaranteed, especially with regard to reproductive screening where couples may be faced with the choice of avoiding or terminating a pregnancy. In contrast, in some countries, and in most states in the United States of America, newborn screening is a legislatively mandatory program, and parental consent is rarely required. The argument here is that it is society's obligation to overrule the parental decision to refuse screening that has a minimal risk of harm while having potential life-saving consequences for the child.

In screening, people should be given enough time to reach a balanced, well-informed decision. This requirement may be difficult to realize in prenatal and neonatal screening, but every effort should be made to inform pregnant women about the decision to come forward as early in pregnancy as possible. People should have ample opportunities for pretest consultation and privacy protection, and permanent quality control of all aspects of the program should be ensured. Finally, the financial costs of the program should be taken into account, and alternative strategies for combating the health problem should be considered. All this information should make it possible to compare and weigh the benefits and drawbacks of the program in a given context. The final balance should be clearly biased toward the benefits. It is desirable to have an authority to supervise all (genetic) screening programs in a country or larger region.

The complexity of genetic screening makes it a multidisciplinary area. Genetic-screening programs can be envisioned as a conceptual framework with three integrated levels (i.e., laboratory, clinical, and management), involving many stakeholders such as laboratory specialists, medical doctors, psychologists, epidemiologists, sociologists, jurists, ethicists, economists, patient organizations, representatives of the community, and policy makers (Andermann et al., 2010).

Quality of the Screening Test Method

Before screening can be offered, a reliable and valid test should be available. A test result is termed positive when it points to the presence of the feature sought after. Similarly, a result is said to be negative when it indicates the absence of the feature. Both results, however, may be false, resulting in false positive and false negative test results, respectively. The probability that a certain screening test result is true or false depends on the prevalence of the feature and two test characteristics: sensitivity

and specificity. Sensitivity refers to the proportion of cases in which the presence of the feature is identified by the test. Specificity is the proportion of cases in which the absence of the feature is correctly identified by the test. The predictive value of a test result, either positive or negative, indicates how often that test result is correct. In many cases, it is not possible or feasible to have a test that is 100% sensitive or specific. In neonatal screening, the missed affected cases should be avoided as much as possible, which may result in a higher number of false positives. The lack of perfect specificity can be countered by subsequent diagnostic workup. When the screening involves a DNA test, specificity is usually very high. If, in the cascade approach, family members are tested for the same mutation as has been found in the proband, sensitivity is also very high. In the case of a test with imperfect sensitivity (e.g., 90%), the imperfection is multiplied in carrier couple screening (81%).

With an increasing number of disorders tested for, for example in neonatal screening, the challenges of interpreting results are increasing with ambiguous results, incidental findings, and overdiagnosis (i.e., a screening-based diagnosis in a person who is destined to remain asymptomatic or whose course of disease is not changed by early diagnosis) (Burke et al., 2011).

Psychosocial Impact of Genetic Screening

Because the potential impact of genetic screening is considerable, the advantages as well as the disadvantages of genetic screening should be considered carefully before deciding to offer a specific screening program as a matter of course. The availability of genetic screening may also have its drawbacks. Among the potential drawbacks of genetic screening are the difficulty of making an informed decision for a test that is offered but unasked for, and the psychosocial implications of a positive, false positive, or unfavorable test result.

Genetic risk information is complex and often replete with uncertainties that are associated not only with the hereditary nature of the disease but also with the degree of informativeness of the test results, the effectiveness of preventive measures, and the variability of expression of the disease (incomplete penetrance). The underlying assumption that accurate perception of risk could help people make informed and individual decisions seems to be based on the principle of the autonomous and rational decision maker. From this perspective, the most important goal of genetic education and pretest counseling is to provide people with all relevant information in an understandable way. It is therefore important to find the best format for communicating risks and to stimulate a rational trade-off of pros and cons of several options. Research has shown, however, that people find it difficult to understand risks and to make rational trade-offs (Van den Berg et al., 2005). In the case of screening for a hereditary disease, the decision to screen is complicated by the potential impact that test results could have on family members and may put familial relationships under pressure.

Multiple testing – for example, testing multiple carrier-screening panels for autosomal recessive conditions – increases the difficulty of giving sufficient information to reach an informed decision. Moreover, with the increasing possibilities and availability of genetic screening, more and more people are now being confronted with the choice of undergoing screening, for example during pregnancy for fetal anomalies. In many countries, young pregnant women with a low risk of having a child with Down syndrome are offered prenatal screening (Javaher et al., 2010). If they choose screening, they must cope with the possibility of a positive screening result and the implication that confirmation is needed using invasive diagnostics such as amniocentesis, which itself carries a risk of miscarriage. When they decide against screening, they must deal with the feelings that they could have made a different choice (in the case that things turn out badly and the child is affected). The decision for or against screening is not only emotionally complicated but also cognitively complicated.

Screening and waiting for the results may have an emotional impact on people. Many people at low risk are likely to undergo testing for reassurance and hope for a good result. Most of them will receive a negative – favorable – test result. For those who perceive themselves as being at risk, this is reassuring, but the news will perhaps be learned at the expense of knowing that they were at risk in the first place. A positive screening test is obviously upsetting even if it turns out to be false. In particular in the neonatal stage, an increasing number of parents receive a false positive result as the number of disorders tested for is increasing (Burke et al., 2011).

When test results become available, they need to be interpreted. Mostly, test results also involve uncertainties. A positive test result after prenatal screening for Down syndrome means that the risk of having a child with Down syndrome is higher than a selected cutoff point (e.g., 1 in 200). A decision must then be made of whether or not to confirm this chance estimate with invasive diagnostics, whereby the extra information must be traded off against the risk of a miscarriage. It has been shown that women who make an informed decision for prenatal screening showed less adverse emotional reactions when confronted with a positive screening outcome and seemed to feel more able to make a decision about prenatal diagnostic testing (Kleinveld et al., 2009). Most women having diagnostic tests as a result of a positive screening test for Down syndrome will turn out not to carry a child with Down syndrome, and their anxiety can be considered to be unnecessary.

Testing positive as a carrier of a recessive disease such as cystic fibrosis without actually having the disease can affect one's view of the future and one's optimism about it (Axworthy et al., 1996). Testing for carrier status of cystic fibrosis involves a very large number of mutations, but it is practicable to test only for the most common, resulting in test sensitivity of less than 100%. If tested negative for carrier status of cystic fibrosis, there is still a residual risk and thus no complete reassurance can be given that one is not a carrier, therefore demanding adequate pretest information. It has been shown that a significant proportion of participants who tested negative when undergoing carrier screening wrongly believed that they were definitively not carriers, while some carriers falsely believed that they were only likely to be carriers (Axworthy et al., 1996).

Another complex issue relates to the fact that as a consequence (by-product) of the screening method, in neonatal screening also carriers of autosomal recessive disorders are identified, for example for sickle cell disease and to a lesser

extent for cystic fibrosis. The implications of these results are not always adequately understood by those parents who are informed of these findings.

It could be argued that a poor understanding of genetics in general, the tests, and the meaning and consequences of test results lies at the basis of many of the problems or possible negative effects of genetic screening described in this article. It is therefore very important that the public as well as people with an at-risk status learn more about genetics, how best to make a decision, what it means to have a positive screening result, and so on. Professionals should learn the best way to provide genetic information in such a way that people can make a balanced decision for or against genetic screening and be able to cope with the test results so that the advantages of screening will be maximized and the disadvantages minimized.

New Developments in Genetic Screening

Traditionally, genetic screening was aimed at rare single-gene (monogenic) Mendelian disorders. As more has become known about the genetic background of disease, more attention is being given to screening susceptibility for common multifactorial disorders such as diabetes, heart disease, and psychiatric disorders (Andermann et al., 2010). However, testing based on these genetic variants, even in addition to traditional disease risk factors such as obesity and hypertension, still shows limited predictive value for disease and few health benefits to the individual user. Despite these limitations, testing is commercially offered directly to consumers, mostly on the Internet (*see* Direct-to-Consumer Personal Genetic Testing). In the future, as more genetic variants associated with cancer risk are identified, cancer-screening programs such as those aimed at breast cancer may be based on genetic risk profile, which has the potential to be more effective than the current mammography screening program based on age (Pharoah et al., 2008).

With the advances in genetics research and technology, genetic screening for an increasing number of medical disorders is possible. Questions are raised regarding whether screening for a particular disorder should be routinely performed or whether screening programs should be expanded, for example in neonatal screening. A successful newborn-screening program requires a suitable test and effective follow-up, such as rapid access to treatment, which may not always be the case.

New developments are also being achieved by high-throughput technologies such as genome-scale tests to measure multiple genetic differences in the genome simultaneously. These techniques are expected to have a great influence on the screening practice, especially since the costs of these tests will further decrease (Burke et al., 2011). One example is massively parallel DNA sequencing of cell-free fetal DNA in maternal blood to detect fetal chromosomal abnormalities. This means that for Down syndrome screening, a simple blood sample of the mother is enough to perform testing (noninvasive prenatal diagnosis (NIPD)). One of the main advantages of this technique for detecting Down syndrome, as opposed to the currently used combined test, is that the accuracy is very high and about 98% of the invasive diagnostic procedures could be avoided (Chiu et al., 2011). In addition to NIPD testing for aneuploidies, it has been shown that noninvasive whole-genome sequencing of a fetus is possible (Kitzman et al., 2012). Another example is the simultaneous analyses of carrier status of multiple recessive disorders using genome-scale screening techniques (Bell et al., 2011), which may be applied in preconception carrier screening. Genome-wide testing may also apply to the screening of IVF embryos. In that case, PGS is not just to select embryos with the highest chance of survival but also to select an embryo that will grow into a child that is as healthy as possible (Health Council of the Netherlands, 2010). These developments clearly have the potential to change the screening landscape, but obviously also raise new ethical, economic, and societal issues that need to be addressed.

Genetic Studies of Behavior: Methodology

Abstract

The goal of genetic research on behavior is to understand how genetic variation influences behavioral variation. Multiple methods have been used, from genetic influences inferred from familial resemblance to measured genes using molecular genetic methods. In this article, first, we discuss some historical background in genetic studies of behavior. Second, we focus on contemporary issues in the study of gene structure and function, emphasizing the methodological unity of most approaches. Contemporary issues include (1) measuring variation, (2) experimental methods, and (3) statistical methods. Finally, we discuss methodological challenges likely to continue in future genetic studies of behavior.

The goal of genetic research on behavior is to understand how genetic variation influences behavioral variation. A wide variety of methods have been used, from genetic influences inferred from familial resemblance to measured genes using molecular genetic methods.

Humans have 26 pairs of chromosomes containing approximately 30 000 genes – identifiable units that contain the code for making specific proteins. Genes range in size, but altogether comprise $3.2\times10e^9$ *base pairs*, the fundamental letters in the genetic code. The genetic sequence of humans overlaps about 99% with that of chimpanzees, and all humans are identical at more than 99.9% of their base pairs. Genetic studies of individual differences focus on this relatively small amount of genetic variation, the *genotype*, and how it relates to variation in behavior, the *phenotype*.

Genetic methods and analyses have roots in the nineteenth century, specifically in Charles Darwin's well-known ideas on evolution and Gregor Mendel's work on the mechanisms of heredity in plants. Many techniques used in genetic analyses of behavior originated in the agricultural sciences in efforts to modify the size and health of plants and animals. These were further developed in the medical sciences to identify and control sources of disease, and are now used to study behavioral phenomena.

In this article, we discuss some of the historical background in genetic studies of behavior; then, focus on contemporary issues, emphasizing approaches used to study phenotypes that are common in the general population rather than rare conditions. This is an updated version of a prior article by McArdle and Allison (2001). We do not address important issues related to the applications of genetic information such as genetic testing and screening, ethical use of genetic information, cloning, and genetically modified organisms (see cross references for articles covering these topics).

Classical Methods in Genetic Studies of Behavior

Until recently, human genotypes were difficult to measure and often treated as unobserved or latent attributes. Analyses of family trees or *pedigrees* provided some of the first scientific evidence for establishing the contributions of genetic variation to clinical phenotypes. Tracing the pattern of inheritance through multiple generations of a family provides evidence about the mechanism of transmission – whether dominant or recessive, sex-linked (on the X or Y chromosome) or autosomal (carried on the other 22 pairs of chromosomes). For example, Sir Francis Galton studied the pedigree of the English Queen Victoria, Prince Albert, and their descendants to study the pattern of transmission of the bleeding disorder, hemophilia. The pedigree method has been highly successful for identifying Mendelian conditions – rare categorical outcomes determined by a single gene – but it is not as useful for studying behavioral variation in the normal range, which is mostly likely influenced by multiple genes as well as environmental factors.

Another source of evidence for genetic influences on behavior is selective breeding studies with nonhuman animals. Seminal selective-breeding studies of learning were conducted by Robert Tryon in the 1930s (Tryon, 1940). In these studies, a heterogeneous stock of rats was tested on a maze. The observed performance on the learning tasks was used to classify groups of 'dull' and 'bright' rats. Those within each group were allowed to mate and produce offspring, which were then tested on the maze and classified. After accounting for some deleterious effects from inbreeding, this successive selection led to distinct strains of 'maze-bright' and 'maze-dull' rats within relatively few generations, thereby demonstrating the importance of genetic influences on a complex behavioral phenotype.

Francis Galton also studied resemblance among family members for continuous phenotypes such as height and intellectual achievement. He reported that individuals born to higher social classes attained higher educational and social standing than those born to lower classes. These family studies were not controlled experiments, so the impacts of genotypes and environments could not be separated. However, the ideas from family studies were combined with experimental concepts derived from animal research to create a novel class of methods based on correlating the behaviors of individuals in atypical groups of families, including twins, adoptees, half-siblings, and other genetically informative family groupings. These methods were discussed and expanded in the early twentieth century by many researchers (e.g., Thorndike, Siemens, Merriman, Fisher, as described in Spector et al., 2000).

Statistical models of inheritance were defined by synthesizing the quantitative rules of Mendelian inheritance with the

correlation decomposition developed by statistician R.A. Fisher and subsequently by many others, including R.B. Cattell, J. Jinks, and D. Fulker (see Falconer and Mackay, 1996). Another important development was the recognition that most phenotypes are measured imperfectly, and this measurement error will reduce the observed correlation among relatives or between genotype and phenotype. Geneticist Sewell Wright (1920) developed path analysis to estimate genetic influences separately from environmental and 'chance' factors. Later, multivariate statistical methods were developed to allow analyses of *latent* phenotypes, derived from multiple measures or other statistical methods for reducing error (e.g., McArdle and Goldsmith, 1990; Neale and Cardon, 1992).

In the remaining sections of this article, we describe the methods for measuring genetic variation, contemporary methodologies used in genetic studies of behavior, and consider some issues for future research.

Measuring Variation in Gene Structure and Function

The final decade of the twentieth century brought a revolution in molecular genetic methodology, including direct measurement and experimental manipulation of variation in genotype and gene expression. Direct sequencing of genetic regions of interest is emerging as a method for studying behavioral phenotypes; but, more commonly applied methods utilize genetic *markers*, sequences with a known position on the genome at which there is measurable genetic variation between individuals. Studies based on positional information capitalize on the fact that Mendel's law of independent assortment does not hold for genes that are physically near each other on the same chromosome. This means that they are transmitted together from parents to offspring to a degree that is directly related to their physical proximity on a chromosome. Commonly used markers include smaller variants, or *single nucleotide polymorphisms* (*SNPs*) that differ at a single base pair and thus have at most four possible forms (A, G, C, or T). The larger variants have multiple forms based on size or structure (e.g., CNVs, microsatellite markers). The alternative forms of either the smaller or larger variants are referred to as *alleles*. Genes range in length from 800 to 2.4 million base pairs, providing thousands of locations within a gene at which individuals may vary in alleles and that could serve as markers. Some markers code for functional variation hypothesized to contribute directly to a phenotype, whereas others correlate with genetic function based on having a location proximal to the functional variant.

Cosegregation of markers and phenotypes is studied using several different designs, including linkage and association (Elston, 1998). Linkage studies are similar to the pedigree method in attempting to identify genetic regions that are more frequently transmitted with the phenotype than would be expected by chance based on the degree of genetic relatedness of family members. These family-based methods have been successful for identifying genetic variants responsible for rare conditions and conditions that have *etiological heterogeneity* – when there are different genetic mutations in different families. Their usefulness is less clear for studying traits that are continuously distributed in the population and for which there are many contributing genetic variants that are common in the population and have small effects. Another disadvantage of linkage studies is that they are typically designed to investigate a single phenotype (e.g., schizophrenia), requiring a great amount of effort to locate, assess, and genotype a large sample of affected individuals and their family members.

Association studies estimate the statistical association between a genetic marker and phenotype in a variety of designs, with the number of markers ranging from a single *candidate gene* (selected for its hypothesized functional relation to the phenotype) to exploratory methods such as *genome-wide association studies* (*GWAS*) that may include millions of markers. Sampling for association studies includes case control (selected for presence or absence of a categorical phenotype) and population samples, both of which allow estimates to be made for the association of markers with quantitative phenotypes. Association studies are useful for examining common genetic variants that contribute to complex traits and several genetic variants simultaneously that may have small effects on the traits. Disadvantages include the expense of collecting genetic data on large samples of individuals, accounting for variable gene frequencies within the study sample, and spurious positive associations (see Section Methodological Issues for Future Genetic Studies of Behavior).

Newer analysis methods contain features of both linkage and association, including family-based association tests and as well as methods for analyzing GWAS data obtained from relatives or multivariate phenotypes.

Experimental Methods to Study Genetic Variation

In addition to the correlational methods used for studying human phenotypes, studies of animals allow experimental methods for more precise understanding of gene activity. Most of this work is done with rodents as they have short-generation times, and mammals are most applicable for studying phenotypes that parallel human traits. The usefulness of animal models is most clear for physiological responses (e.g., drug sensitivity) but is less evident with more complex phenotypes.

Conceptually, the simplest method for locating trait-influencing genes is selective-breeding studies. These studies are based on measurements of the frequencies of genetic variants in an outbred (genetically heterogeneous) population. As subsequent generations are bred to produce higher and lower values of the trait, genetic variants that change in frequency across generations can be concluded to influence the trait or be linked to variants that do.

A more complex but efficient method uses recombinant inbred (RI) strains – lines of animals that have been inbred until they are genetically identical. If the lines differ in their average value for a phenotype (when all are reared under identical conditions), this implicates genetic variation between lines in producing the phenotype. Because members of a strain are identical, genotyping only needs to be conducted for one animal. Researchers can use databases cataloging the genetic variation among inbred strains to conduct genotype–phenotype studies. More complex methods involve intercrosses between inbred strains, analyses of multiple markers,

multivariate analyses with multiple phenotypes, selective sampling, and other enhancements.

In addition to variation in what a gene produces, there is variation in gene *expression*, how gene activity varies across development or in response to internal or external events. Genetic expression studies use microarrays, which are small silicon chips designed to simultaneously measure the expression of thousands of genes. Typically, expression is assessed across several different experimental conditions. For example, expression of genes active in neural response might be studied under several levels of ethanol exposure.

One limitation of approaches based on experimental organisms is that they study genetic variation as observed within a fixed range of environmental conditions. They do not identify genes that are fundamentally important to a phenotype but for which all individuals within a population have the same alleles. Similarly, some genes may not create phenotypic variation within the range of environments that are studied, but could produce important phenotypic variation under environmental manipulations produced experimentally or through ecological changes.

Other experimental techniques study gene function by altering particular genes and observing the behavioral effects. One of the most common types of these induced mutation studies is a 'knockout' animal, where the activity of a specifically targeted gene is disrupted. Another method is using transgenic designs that introduce genetic variation from one strain into another to study how gene effects change when expressed in a different genetic background.

Contemporary Statistical Methods Based on Measured Genotypes in Humans

Most behavioral phenotypes are assumed to be continuously distributed and multifactorial polygenic – arising from multiple genetic as well as environmental sources. Estimates of the variation attributable to these sources are based on classical biometric genetic theory, which specifies the relations among the underlying components contributing to a trait (e.g., Falconer and Mackay, 1996). Standard assumptions are that the effects of involved genes are additive, segregate independently in the population (i.e., the variants at one gene are uncorrelated with the variants at others), are not sex-linked, and do not influence spousal selection.

Estimating Sources of Family Resemblance

These biometric assumptions are important because they lead to statistical expectations about the observed correlations among pairs of relatives. Specifically, if these assumptions hold, the genotypes of pairs of first-degree relatives (full siblings, fraternal twins, and parent–offspring) correlate 0.50, genotypes of second-degree relatives (grandparents–grandchildren, aunt–niece, half-siblings) correlate 0.25, and those of third-degree relatives (cousins) correlate 0.125. Unrelated individuals living together, such as step-siblings or parents with their adopted children, are expected to have uncorrelated genotypes. If all resemblance between relatives in a family is due to genetic sources, the correlations between their observed phenotypic scores are expected to be proportional to the correlations between their genotypes.

Nongenetic familial influences are implicated in these models by the extent to which the pattern of familial resemblance differs from genetic resemblance. If phenotypes are influenced by shared environments (e.g., rearing or social background), the highest correlations would be found for pairs of twins and similar-aged siblings (including step or adoptive siblings), lower correlations for parents with children, and still lower from related individuals who have not lived together. Under a purely environmental etiology, the correlations of adoptees with their adopting parents and siblings should be as high as for any other children, and related individuals reared in different environments would be uncorrelated. A model that includes both genetic and environmental sources of familial resemblance would produce estimates intermediate between these two. All such models can include measurement error (unreliability) and the influence of experiences unique to particular individuals.

Structural equation models are used in behavior genetics to organize, estimate, and test aspects of these theories of underlying influences. In psychometric models, the observed phenotype or trait can be considered a combination of true score and specific factors, including error of measurement. Behavior genetic models partition true-score variation into unobserved variables representing biometric hypotheses: additive genetic scores (A), dominance and other nonadditive genetic scores (D), common family environment (C), and individual-specific environmental sources (E). The goal of the structural analysis is to use the data from relatives to estimate the total impact of each component. In studies of a single phenotype, the E component includes measurement error. These can be separated when the trait is a latent factor based on multiple measures.

Family, adoption, and twin designs rely on different assumptions and can provide different estimates of the theoretical components. In all cases, the goal is to obtain genetic and environmental estimates that will generalize to explain behavioral variation in the general population. To the extent that the samples studied are not representative, the resulting estimates may be biased.

Family and Adoption Designs

Figure 1 shows several path models representing the variance components that can be estimated using different configurations of relatives. In practice, nonadditive genetic sources (D) are less commonly found, so these examples focus on the other components. Figure 1(a) depicts a nuclear family design. In this model, resemblance between parents and offspring cannot be partitioned into separate additive genetic (A) and common family environment (C) sources.

In the adoption design shown in Figure 1(b), these A and C components are (theoretically) separable: the only source of parent–child resemblance is through environmental sources. By comparing differences in resemblance among family members in the adoptive versus biological family designs, an estimate of the additive genetic contribution to phenotypic variation can be obtained. A potential limitation of the adoption design is selective placement, in which adoptees are not

Figure 1 Latent variable path models for estimating sources of trait variation from different types of family designs. Boxes indicate measured variables (Trait score), circles represent unobserved theoretical variables. One-headed arrows are fixed regression coefficients. Two-headed arrows represent estimated variances or correlation coefficients. Latent variables are: A = additive genetic variation; C = common family environment; E = individual environment and measurement error. (a) Parent offspring design. Children resemble their biological parents due to transmitted genetic and environmental factors, which are not separable. (b) Adoption design. Children resemble their adoptive parents only due to environmental factors, allowing separation of genetic and family environmental effects. (c) Biological sibling design. Siblings reared together resemble each other due to transmitted genetic and environmental factors, which are not separable. (d) Sibling pairs with different degrees of genetic correlation can be used to separate genetic and family environmental effects.

randomly assigned to their adoptive families. To the extent there is positive selective placement that is not accounted for in the model, family environmental effects may be overestimated. Another limitation is that adoptees and adoptive parents may not be representative of the trait being studied – with adoptees more likely to have biological parents with disadvantaged backgrounds (including their prenatal environments) and adoptive parents coming from higher socioeconomic backgrounds screened for serious psychopathology.

Sibling and Twin Designs

Another common set of designs is based on the resemblance of siblings reared in the same family. These models do not address mechanisms for transmission between generations, as do the parent–offspring designs, but they are better for studying traits that are influenced by cohort- or age-specific factors. Figure 1(c) depicts sources of resemblance between pairs of full biological siblings. As in the parent–offspring model 1(a), genetic and shared environmental factors are confounded. However, if the design is expanded to include siblings with varying degrees of genetic correlation, represented by r_A in Figure 1(d), the A and C components can be distinguished.

The most influential sibling design is the twin design, which compares the resemblance for a trait among identical (monozygotic, MZ) twin pairs to that of fraternal (dizygotic, DZ) pairs. The genotypes of MZ pairs are correlated 1.0, whereas those of DZ pairs are correlated 0.50. MZ and DZ pairs are assumed to be equally similar for aspects of the common environment relevant to the trait being studied. If the pair correlation for a trait is the same for MZ and DZ pairs, common environmental sources (C) are implicated as the source of family resemblance and genetic sources (A) are not involved. To the extent MZ pairs are more similar than DZ pairs, genetic sources are implicated. Comparing the similarity of male–female DZ pairs to that of like-sex DZ pairs provides estimates of sex-specific genetic and environmental factors.

Key assumptions in the twin design are that mating of parents is random with respect to the trait and that the trait-relevant environments of MZ and DZ pairs are equally similar. To the extent that mating is trait-related, genetic influences will be underestimated. To the extent that the environments of MZ pairs are more similar than those of DZ pairs, genetic influences will be overestimated.

Comparisons of other types of siblings follow the same logic as in the twin design: if siblings with a higher genetic correlation are more phenotypically similar than pairs of

siblings with a lower genetic correlation, genetic sources are implicated as contributing to the trait. The assumed correlation of the genotypes of full siblings is 0.50, half-siblings is 0.25, and step-siblings is 0. In practice, there may be a small correlation between the genotypes of step-siblings because spouses in remarriages tend to be similar to those from prior marriages.

Twin studies are preferred to nontwin sibling designs because they are statistically more powerful (i.e., require smaller sample sizes) and the assumption of equal environment is considered more valid for twins than for siblings of different ages. Nontwin full siblings tend to be less similar than DZ twin pairs for most behavioral phenotypes. This suggests the importance of age or environmental influences on the phenotype. However, a genetic explanation is also possible; sibling groups usually include some half-siblings who are unaware they do not share a father, making the actual genetic correlation lower than the expected value of 0.50.

Two advantages of the sibling design compared to the twin design are ease of recruitment and sample representativeness. For most behavioral phenotypes, twins are similar to the general population, but they have higher rates of intellectual disabilities, possibly related to higher rates of complications in twin pregnancies and births. Recently, the frequency of DZ twin and other multiple births has increased markedly due to increases in maternal age and use of assisted reproductive technologies. Older age and hormonal treatments increase the chances that multiple eggs will be ovulated in the same cycle. With *in vitro* fertilization multiple zygotes are typically implanted together, resulting in more twin births. To the extent that these interventions are not random, but are differentially employed (e.g., by mothers with greater economic resources), DZ twins in younger samples may not be representative of the broader population. To some extent family, adoption, and twin studies complement each other and hybrid approaches help address the weaknesses in specific designs. Studies of the offspring of twins can distinguish different mechanisms for parent–offspring transmission. In typical twin studies, the 'common environment' includes all nongenetic sources of twin pair similarity. The composition of the environment can be clarified in studies of individuals with different degrees of genetic and environmental sharing including twins, siblings, and classmates, or twins reared apart.

Heritability and Interpreting Genetic Estimates

After biometric model coefficients are estimated, it is common to standardize the unobserved variables, and assuming that the latent scores (A, C, and E) are uncorrelated, calculate the unobserved genetic variance. To compare results for phenotypes with different measurement scales, it is common to calculate the *heritability ratio* (h^2): genetic variance divided by total phenotypic variance. This calculation may or may not account for other components such as shared environment and nonadditive genetic influence (dominance, epistasis). Comparing heritability estimates across samples is complicated by the fact that samples may differ in total variance, leading to much different heritability estimates for the same amount of genetic variation. For example, in a society that provides adequate nutrition for all its people, variation in height would be expected to be nearly all genetic (i.e., high heritability), whereas a society for which the nutritional environment was more variable would have greater phenotypic variation, of which a small proportion would be genetic (lower heritability).

So far, studies using measured gene designs account for only a fraction of the genetic variation that is implicated in studies using twin and family designs. A variety of factors may underlie this discrepancy, including nonadditivity of genetic effects, gene–environment interactions (GxE), and greater measurement error and heterogeneity in methodology in samples included in GWAS studies (see Section Methodological Issues for Future Genetic Studies of Behavior).

Gene–Environment Interplay

As genetic variants influencing behavior are identified, the next goal is to clarify how their expression varies over the life span and in response to environmental variation. Measured gene–environment interactions have been studied extensively in model organisms, but there are few replicated findings for complex behavioral phenotypes in humans. GxE studies are subject to a variety of methodological concerns including multiple testing and using measures of the 'environment' that also reflect genetic variation. Nevertheless, experimental evidence indicates that ideas about genetic effects need to be more dynamic and to consider the impact of variation due to environmental contexts, be they cellular, intrapersonal, or societal.

Methodological Issues for Future Genetic Studies of Behavior

The advent of measured gene technology has been accompanied by an expansion of study designs, analytical methods, and tools for data management. However, in order to apply these methods to the impressive amounts of accumulating genetic data, yet more novel approaches to the research are needed. This final section discusses some of the methodological issues involved and solutions being proposed in analyzing measured genotypes in future studies of behavior.

Sample Size and Statistical Power

GWAS uses a hypothesis-free design for marker selection that represents an unbiased method for identifying multiple SNP markers associated with a complex trait at the same time. Because complex traits are likely influenced by additive and individual effects of multiple genetic variants simultaneously, effect sizes for individual variants identified through GWAS are typically very small and very large sample sizes. Often samples including tens of thousands of individuals are required to detect statistically significant associations, depending on the effect size and design (i.e., population vs case-control). With this prohibitive size requirement, GWAS are often designed to test only alleles that are more commonly occurring in the population (i.e., SNP frequency greater than 5%).

To accommodate testing on such large samples, contemporary GWAS methods are designed for time and cost

efficiency. GWAS takes advantage of using fewer markers to capture allelic variation in a gene region, rather than testing each individual SNP. Of the millions of SNPs in the human genome, testing a fraction of SNPs in GWAS are sufficient to represent all common variation across the genome, depending upon the number of marker SNPs estimated to segregate together. Minimizing the number of SNPs optimizes GWAS for identifying associations between those occurring in higher frequency (versus rare SNPs) as well as traits that occur more commonly in the population (versus rare diseases).

Amassing the large sample sizes required for GWAS is often beyond the scope of a single research group. This has spurred the creation of large collaborative networks involving hundreds of investigators. Greater collaboration is a positive development for science, but the validity of combining existing data sets depends on comparability of measurement, sampling, and population ancestry. Phenotypes that can be combined across samples are ones that are easily measured (e.g., height) and may be of less interest for behavioral and social science.

As in other areas of science, the statistical power in measured gene studies can be increased by reducing measurement error. Using more precise measures or creating latent variables from multivariate and longitudinal data substitutes for greater sample sizes (Wong et al., 2003) and reduces problems associated with pooling data across studies.

Type I Error and Replication

The efficiency of being able to test millions of SNPs in single scans brings forth issues of multiple testing, which can yield a high rate of false positives (Type I error), and requires adjustment of statistical significance thresholds. A commonly cited threshold for genome-wide significance is $p < 5 \times 10^{e-8}$, based on an alpha set to 0.05 and testing 1 million SNPs (Risch and Merikangas, 1996). However, many researchers calculate their own probability-level adjustments or use less stringent criteria to avoid false negatives (Type II error). Current consensus among the field is that the reliability of association results should be based on replication in independent samples rather than significance levels. Many journals will not consider publication of association results unless there is evidence of replication in an independent sample. An alternative is using an internal replication design where GWAS is conducted in one portion of the sample, then the top SNPs are tested for association in the remaining sample.

Candidate gene studies reduce the multiple testing problem by hypothesizing an association between genetic loci and the phenotype, often from *a priori* evidence from GWAS, linkage, or gene expression studies. Early candidate gene studies typically employed a limited set of gene variants (or nearby markers), but customized chips for testing genes hypothesized to be involved in a particular biological pathway or condition (e.g., cardiovascular disease, addiction) include tens of thousands of SNPs, requiring modification of probability levels. It is common to apply Bayesian methods (e.g., Benjamini and Hochberg, 1995) to adjust for prior evidence of association in order to safeguard against spurious associations, while helping to maintain statistical power. Positive associations implicating a biological pathway require replication in independent samples or through experimental studies.

Population Stratification

A nontrivial concern for association studies is when the trait and genetic variants are correlated from population stratification rather than because the allele is causally involved. Population stratification, or population structure, occurs when ancestral differences between subpopulations in the study sample result in different allele frequencies between them (Tian et al., 2008). For example, spurious gene–trait associations can arise when ethnic groups differ in both allele frequencies and trait distributions. One way to detect stratification is genomic control, testing if genetic markers that are not hypothesized to be associated with the phenotype deviate from the expected distribution (Devlin and Roeder, 1999; Freedman et al., 2004). A common method for minimizing the effect of stratification is adjusting for ancestral similarity. This is done by conducting principal components analysis (PCA) to identify a subset of genetic variants, or ancestry informative markers (AIMS), that serve as quantitative markers for assigning ancestral similarity (Price et al., 2010). Then, top principal components, those that explain the greatest variance, are then used as covariates in association models.

Future Challenges

A great deal of progress has been made in developing new methods for studying the contribution of genetic variation to human behavior, with more innovative approaches rapidly being disseminated. It will be an ongoing challenge for data management and analytic tools to keep pace with the vast amounts of information generated by microarray chip technology, sequencing advancements, and future developments in genetic networks.

Abstract

As soon as fundamental principles of genetic inheritance were clearly established in the early twentieth century, anthropologists began using these principles and new empirical data to illuminate long-standing problems of human variation and primate phylogeny. Initially focusing on human blood characteristics, geneticists quantified regional differences in ABO genotype, and tried to correlate these differences with more traditional osteometric assessments of variation. Anthropologists were especially interested in alleles like the sickling trait, which had adaptive significance. When blood samples became available from other primates, in midcentury, it became possible to construct phylogenetic trees based on genetic data, and to compare these results with the fossil record. After World War II, field expeditions were organized by anthropological geneticists to collect far-flung samples of human genetic material, along with new cultural and linguistic data, in the hope of finding correlations, thereby detecting evolutionary trends and reconstructing human migration. With the addition of ancient DNA techniques to the anthropological repertoire in the 1980s, all four fields of anthropology – ethnology, archaeology, linguistics, and human biology – became intimately involved in genetics research, both individually and in cross-disciplinary research. The immediate research agenda for anthropological genetics includes (1) human origins; (2) prehistoric migration; (3) coevolution of biology, language, and culture; and (4) variation and adaptation to modern environments.

The fields of anthropology and genetics maintained a tense coexistence throughout the twentieth century, sometimes complementary to one another (as in the decades immediately following World War II) and sometimes antithetical to one another (as in the eugenics movement of the 1920s and the genetic essentialism of the 1990s). The reason is that the self-interest of geneticists is sometimes perceived to lie in the assumption that genetics determines the most important aspects of a person's life or identity (Nelkin and Lindee, 1995), which would run counter to the anthropological focus on culture. Normative human genetics after World War II, led by Theodosius Dobzhansky, James V. Neel, and Luca Cavalli-Sforza, tended rather to emphasize the complementarity of the two fields. Here, human genetics would form a foundation for the study of human microevolution, and its primary data would be biochemical 'markers' of ancestry, or intergenerational continuity. Within anthropology, then, normative genetic research came to incorporate four kinds of questions: (1) patterns of human variation; (2) the phylogenetic relationships among humans and other primate species; (3) the migration and adaptation of human populations, or microevolution; and (4) the relationships among biological variation and other kinds of human variation, especially in language and culture. Additionally, there are areas of overlap between genetics and humanistic anthropology, including medical anthropology (Taussig, 2009), economic anthropology (Pálsson, 2007), bioethics (Brodwin, 2005), and political ecology (Stone, 2010).

Human Variation

When laboratory techniques for studying Mendelian traits first became available, international anthropology had just emerged from a controversy over racial typology during which Franz Boas, recognized by many as the founding father of American anthropology, had repudiated to the satisfaction of most anthropologists the racial theories to explain civilization that had been popular in the late nineteenth century. Originally trained as a physicist, Boas presented data and arguments between 1910 and 1913 showing that 'race,' 'language,' and 'culture' were three independent phenomena that, he asserted, should all be studied by anthropologists, but using different kinds of theories and techniques.

Shortly after World War I, the earliest population genetic studies of human blood groups seemed to undermine the ideas about race that physical anthropology had traditionally employed, although it would be several decades before the meaning of this discordance became clarified (Marks, 2012). After World War II, as human genetics became increasingly redirected toward real genetically based medical pathologies (such as sickle-cell anemia), rather than imaginary genetically based social pathologies (such as feeblemindedness), it became clear that the simple rules of Mendelian inheritance applied only to the inheritance of biochemical variants and pathological conditions resulting from the breakdown of specific genes (the repository for medical genetic conditions is Online Mendelian Inheritance in Man, http://www.ncbi.nlm.nih.gov/omim). The interesting physical attributes of human variation (such as height, complexion, facial form, hair form, and body build), however, are all the result of more complex hereditary and developmental physiologies, involving the coordinated activities of several genes and regulation of their products, in specific environmental, genetic, and cultural contexts.

For anthropologists, the major theoretical model that emerged to describe human genetic variation in this period was the cline, the gradual geographic change in the frequency of an allele, which also served to undermine further the idea of racial typology. Both physical form and genetic variation seemed to

vary across the human species in a continuous, quantitative fashion.

Some patterns that emerged from the analysis of clines conformed to more general biological principles pertaining to other animals. It was found, for example, that Gloger's, Bergmann's, and Allen's Rules for variation within a mammalian species (pertaining to pigmentation, mass, and limb length, respectively) were also crudely valid for the human species, reflecting adaptation to the different latitudes, climates, and environments inhabited by local human populations. Since these traits were so clearly adaptive, it was suspected that other patterned traits, with definite clines, likewise reflected genetic adaptation to local conditions. Alternatively, they might be the track of large-scale migrations of ancient peoples.

Adaptation

The most forceful new example of human genetic adaptation was presented by Livingstone (1958) with his study of sickle-cell disease, especially as it existed in Africa. In addition to presenting convincing evidence of several types to prove that sickled blood cells were a long-term genetic response to the presence of malaria, Livingstone's work illustrated several other lessons in anthropological genetics. First of all, it was the heterozygote (a person with two different alleles for a specific gene) or carrier of hemoglobin S (HbS) who had the adaptive advantage, not the HbS homozygote (possessing two identical alleles for a specific gene), who suffered from sickle-cell anemia. The second lesson was that an apparent 'disease,' sickle-cell anemia, was on closer inspection actually a successful genetic solution to a largely human-made environmental problem, namely, malaria – stimulated by the widespread presence of mosquitoes, which in turn were attracted by large areas of standing water that were promoted by early agricultural practices. The story does not end in the past, however, as medical anthropology and history are now illuminating complementary anthropological aspects of sickle-cell anemia (Wailoo and Pemberton, 2006; Fullwiley, 2011).

Another highly visible connection between genetic variability, culture, and environment concerns the ability of human adults to digest milk and milk products from dairy animals, an ability that seems to be under genetic control. When mapped geographically, the alleles responsible for adult lactose tolerance in human populations seem to be correlated, in the Old World, with the present and past locations of pastoral peoples (Durham, 1991). Lactose tolerance has arisen in parallel in several different areas, and the most common mutation in Europeans probably spread with the descendants of early dairy farmers (Ingram et al., 2009).

Many correlations have been found between pathogenic diseases and genetic variations. None, however, has been established as firmly as the relationship between malaria and sickle-cell anemia, and other related blood diseases. Different patterns of genetic variation among populations are explained as accidents of demographic history, or founder effects, rather than as adaptive responses of the gene pool. The most famous examples here are genetic diseases that are rare elsewhere but have attained an anomalously high frequency in a particular population, for example, porphyria variegata among the Boers of South Africa and Ellis–van Creveld syndrome among the Pennsylvania Amish – both of which have elevated frequencies because a single seventeenth-century immigrant was both a carrier of the genetic disease and an ancestor of the modern populations. In the absence of plausible and reliable physiology (as in the case of sickle-cell or thalassemia) or plausible and reliable historical records, most other diseases associated with genetic variants show more ambiguous patterns.

More generally, understanding the role that genetic variation may play in health care involves the analysis of risk factors and consequent probabilities (Terwilliger and Göring, 2000). Nevertheless, the presumption of a genetic basis for health disparities carries strong political implications and can hardly be taken at face value (Fullerton et al., 2012) Moreover, the saturation of medical genomics with modern capitalism may compromise the reliability of the scientific information it produces. BiDil, promoted as a cardiac medicine specifically for black patients, was actually supported by no valid evidence that it worked differently or better in blacks than in whites. Nevertheless, racializing the drug extended its patent protection. And far from being a public health service, BiDil's manufacturers charged their black patients far more than they needed to pay for it, since the drug itself was simply a mixture of two other generic drugs (Kahn, 2008).

Population Genetics

With increased funding for science in the United States after World War II, and increased access to field sites, anthropologists began to investigate isolated, small-scale human populations with renewed vigor, often including a biological anthropologist in the research team. The most visible of these joint enterprises was probably the comprehensive study of the Yanomamö, who live in the upper drainage of the Orinoco River in Venezuela and Brazil. In the 1960s, James Neel of the University of Michigan organized a comprehensive multidisciplinary series of field expeditions that investigated the environment, ecology, biology, culture, and social organization of these then little-known people. After a series of books and articles was published over the next two decades, the Yanomamö became not the least known, but one of the best-known tribal societies in the world.

For the genetic part of the research, Neel and Ward (1970) examined six blood systems relatively well known at the time (MNS, Rh, Kidd, Duffy, Diego, and haptoglobin) among 7 villages of Yanomamö, 7 villages of nearby Makiritare, and 12 other tribes of Central and South America. After comparing the different groups, the authors concluded that human evolution might have been proceeding at a pace '100 times more rapid' than previously thought, if these small-scale societies could be taken as analogs of earlier Pleistocene or Paleolithic human peoples.

In the same period, other biological anthropologists were proceeding with similar investigations elsewhere in the world. Working in the Solomon Islands from 1966 to 1973, Jonathan Friedlaender simultaneously undertook studies of demography, anthropometry, genetics, and social structure, seeking

to integrate his results into some general conclusions that cut across these traditional fields of research. Like Neel and Ward, he emphasized the genetics of blood systems, in this case ABO, MNS, Rh, Kell, and Duffy. From this kind of data, Friedlaender calculated phenotype frequency and then allele frequency by techniques described in his major ethnographic work, *Patterns of Human Variation* (Friedlaender, 1975). His most general conclusion, combining results from anthropometry, dermatoglyphics (the study of fingerprints), genetics, and demography, was simply that Bougainville communities tended to exhibit high biological variability within the group, but low variability among the groups, and that some traits, such as skin color, eye color, and hair form, were 'monotonous' on the island, while dermatoglyphic characteristics and some blood system alleles were discontinuous from village to village.

Those expecting that these early studies would provide fundamental insights into the mechanisms of human evolution were soon disappointed. Summarizing a widely shared consensus of opinion in 1974, Henry Harpending concluded that (1974: p. 229)

> *… studies of the genetic structure of small populations have made particular and incidental contributions to formal genetics, to regional history and prehistory, to epidemiology, and to several other fields to which they are peripheral, but … they have not advanced our understanding of human evolution in a global sense. The sample sizes available have been too small to allow reliable inferences about natural selection; the extensive occurrence of what is presumably local random genetic drift has little or no consequence for evolution over long time periods over large areas; and the presumed selective agents in the various environments of these peoples differ greatly so that few of the generalizations which have been put forward hold for many groups.*

Evolution of Primates

Early in the twentieth century, it was appreciated that the relations of primate blood appeared to replicate the relations of primate bodies; that is to say, animals who appeared more similar physically tended to have more similar biochemical properties discernible in their blood. Further, the blood of humans was especially similar to the blood of apes; indeed, by the 1920s, human blood was known to be even more similar to chimpanzee blood than horse blood was to donkey blood.

In the 1960s, Allan Wilson and Vincent Sarich (1967) showed that the biochemical variation distinguishable immunologically in the blood tended to track the time since the species being examined diverged from one another, rather than their degree of adaptive physical difference from one another. In the ensuing decades, this generalization has held up remarkably well over diverse kinds of genetic comparisons. Consequently, genetics tends to show how similar humans are to chimpanzees, not how different we are. The reason is that we do not know how to build a four-dimensional body (an organism) from a one-dimensional set of instructions for it (the DNA). Absenting that information, detectable DNA changes are largely uncorrelated with the adaptive physical variations that characterize the 'major features' of the history of life. Consequently, we know rather a lot about how similar genetically we are to chimpanzees, but almost nothing about the genetic basis of bipedality, language, evaporative heat loss, cooperative breeding, or any of the other significant ways in which we differ strikingly from the apes.

Sarich and Wilson (1967) used the primate molecular data in the 1960s to demonstrate convincingly that *Ramapithecus*, considered to be on a human line 14 million years ago, on the basis of teeth and jaw fragments, was about three times older than the human line itself was, and therefore could not be on the human line. Morris Goodman invoked the genetic similarity of humans and chimpanzees to argue for classifying them together as members of the genus *Homo* (Wildman et al., 2003). This would involve privileging the genetic relationships (in which chimpanzees and humans are extremely similar) over anatomical, behavioral, cognitive, and ecological relationships (in which they are considerably less similar).

Modern studies of primate genetics incorporate inferences about not only systematics and divergence times (Steiper and Young, 2006), but also demography, paternity, conservation, and microevolution.

Methods

The production of genomic data climbed so precipitously beginning in the 1980s that a new specialty, bio-informatics, had to be developed in order to detect patterns in genomic data and to make quantitative, statistical sense out of them.

The most fundamental tools used in genomic comparisons involve (1) the acquisition, isolation, manipulation, and amplification of genetic sequences to be studied; (2) the qualitative and quantitative assessment of patterns of similarity among the samples, for example, inferring the kinds and numbers of mutations needed to transform one DNA sequence into another; and (3) an explanation for the patterns in the history of the organisms.

The study of the human genome has revealed that traditionally defined genes (containing the DNA code for a specific protein) constitute only a small percentage of the total DNA in a human cell. About 90% of the human genome is intergenic, that is to say, lying between genes and thus not classically functional. Moreover, most of a gene itself does not actually code for a protein; it may be transcribed into RNA without being translated into protein. Two obvious conclusions are (1) our classical ideas about the functions of DNA were too narrow and (2) there are some interesting structural features of noncoding DNA. Some noncoding DNA is localized, and consists of simple sequences repeated side-by-side millions of times. Other repetitive DNA is interspersed among the genes, and consists of millions of sequences, each one hundreds or even thousands of bases long, and shot through the genome in apparently random places. This redundancy is characteristic of the genome. Genes themselves are commonly found in clusters, the ancient products of a 'rubber-stamp' process of gene duplication, followed by the mutation-mediated inactivation or alteration of the duplicate gene. Other sites in the genome differ from person to person in the number of segments of a short repetitive motif that may be present. These

polymorphisms are known as variable numbers of tandem repeats (VNTRs) and are particularly valuable in forensic contexts, where a match of several highly variable sites can provide a statistical basis for identifying the person that a particular DNA sample came from.

We can generally measure the intensity of selection on a particular genomic region by its rate of change. Noncoding sequences invariably are more different across species than coding sequences are. The simple reason is that coding sequences are expressed as phenotypes, and have evolved by natural selection to produce a functioning body. Any random change within them (mutation) is far more likely to make that body run worse than better. Consequently, mutations that occur in coding sequences are far more likely than mutations in unexpressed DNA sequences to be 'weeded out' by selection. Establishing the background extent of genetic difference between two species helps to identify regions that are evolving 'too slowly' and may thus be under selective constraints. More rarely, a genomic site may be of interest for evolving 'too fast' and thus possibly be related to the adaptive differences that arose between the species.

Stains

As soon as chromosomes could be observed directly through microscopes, attempts were made to stain them chemically so that bands would appear that might show differences in structure. Initially, the purpose was to discriminate among the different chromosomes of the human karyotype, or suite of chromosomes (22 pairs of autosomes, and a pair of sex chromosomes), so they could be counted and identified. During the course of this research, it also became apparent that patterns of stains on a particular chromosome might vary from one individual to another within a population. In addition, when it was noted that certain patterns of staining were characteristic of particular species, yet another method became available for evaluating the phylogenetic relationships among apes and humans. Although several correlations have been established between the observable banding pattern of chromosomes and the DNA sequences they contain, the staining difference presumably results from a higher-order property of DNA (i.e., its three-dimensional folding).

Biotechnological Breakthroughs

The age of biotechnology was made possible by the development of several laboratory methods. The first was the discovery that biomolecules migrate in an electric field, and can be separated from one another and isolated; this is known as electrophoresis. The phosphates in DNA give it a negative charge. Embedded in a semisolid matrix, then, DNA moves toward a positive pole, its shortest fragments moving fastest. Being able to separate DNA molecules from one another forms the basis of all subsequent DNA research.

The second technical breakthrough involved the isolation and purification of naturally occurring enzymes that modify DNA, and can be used to manipulate it in predictable ways. One such class of enzymes is endonucleases, which cut DNA at specific sites (such as GAATTC for the enzyme called EcoR1). Many such enzymes became available in the 1980s, permitting the construction of 'maps' of the DNA where different enzyme cut sites are located.

Another class of enzymes permitted the development of the third technical breakthrough, the polymerase chain reaction. Here, the enzyme is a DNA polymerase, which adds the appropriate complementary nucleotide to produce a stable, double helix from a single-stranded DNA template. By alternating cycles of heating (to dissociate the double helix into single strands of DNA) and replication (using the polymerase to fill in the opposite strand), small amounts of DNA can be amplified sufficiently to be analyzed (Hillis et al., 1996). This is applicable in modern forensic contexts as well as for organic remains that are thousands of years old.

Chromosome Mapping

A major objective of human genetics research is to locate all genes on their respective chromosomes as well as to identify all the other functional regions of DNA, including some formerly dismissed as 'junk.' One technique for gene mapping involves the use of genetic markers, like the restriction enzyme sites described in this article, or other DNA sequence variants. Because many of these are relevant to diagnosing human disease, high levels of funding were made available to the Human Genome Project to identify the location of these variable sequences or 'polymorphisms.' This support has led to the development of very fast computer and molecular technology and machinery, and much of the resultant data appear in easily searched form on the World Wide Web.

Mitochondrial DNA

Most human genes reside in the nucleus of the cell and occur in two copies, one each inherited from the mother and the father. However, the body or cytoplasm of each cell also contains structures known as mitochondria, which are involved in the production of energy for the cell and contain their own DNA. This DNA is special in many ways. At fertilization, the mitochondria of the ovum are transmitted to the offspring, but the mitochondria of the sperm are not. Thus, mitochondrial DNA (mtDNA) is inherited in a strictly maternal manner, such that (unlike chromosomal DNA, in which a child is equally related to father and mother), mitochondrially a child is a clone of its mother and unrelated to its father.

Since mtDNA is haploid (contributed by only one parent) rather than diploid (from both parents) in form, it does not recombine during replication, and over time, as sequence variations accumulate through mutation, it produces distinct, diverging lineages of mtDNA sequences. This variation can be used to reconstruct the mtDNA of the common ancestor (the coalescent sequence) from a sample of mtDNAs collected from individuals alive today. Because the mitochondria are so numerous in the cell, mtDNA can be recovered much more easily than DNA from the nucleus.

The mtDNA chromosome takes the form of a small ring of 16 500 base pairs (16.5 kB), which was entirely sequenced by 1981. In a famous 1987 study, the structure of the mtDNA tree from 147 people was announced, which 'coalesced' on a woman nicknamed 'mitochondrial Eve,'

deduced to have lived in Africa about 200 000 years ago, and whose 'modern human' progeny had emigrated from Africa and repopulated the world, which was at that time occupied entirely by earlier forms of human, such as Neanderthals (Cann et al., 1987).

mtDNA has become very popular in 'recreational ancestry studies,' in which a client's mtDNA is matched against a global reference sample, and clients receive information on their genetic ancestry. However, since (1) the matches are very nonspecific, (2) the world is poorly sampled, and (3) seven of your eight great-grandparents are invisible to this analysis (it only studies your mother's mother's mother), this kind of study has proven somewhat more valuable commercially than scientifically (Bolnick et al., 2007).

Y Chromosomes

Certain regions of the Y chromosome are very stable and do not recombine during meiosis, but are passed on clonally from father to son. Again, while it has some scientific value, by comparing the geographical distributions of mtDNA and Y-chromosome lineages in attempts to reconstruct the migratory practices of prehistoric peoples, much of its use is commercial. Here, clients can learn, for a price, whether they have a Y chromosome inferred (often dubiously) to have belonged to Genghis Khan, Thomas Jefferson, or Moses (Thomas et al., 1998; Jobling, 2012).

Repetitive DNA

Although the picture is constantly changing, researchers at this point recognize three general categories of tandemly repeated sequences (VNTRs), which are classified by length. They are satellites, the longest sequences; minisatellites, defined as sequences that are 500–40 000 base pairs in length, usually consisting of five or fewer repeated nucleotides; and microsatellites, which tend to be short and simple in motif, even consisting of repeats of a single base pair, or a doublet or triad of nucleotides (e.g., CACACA or CAGCAG).

These short, apparently neutral sequences are useful to anthropologists because their rate of mutational change is much higher than the single nucleotide mutation of DNA, so that more variation is detectable across humans and human populations. Thus, minisatellites and microsatellites, like mtDNA, may provide a finer control of historical relationships among individuals and the populations they represent than variation in the nuclear DNA.

Grand Synthesis

The history of gene pools is the history of the interaction of several biological and cultural forces. The first is mutation, or the production of new alleles; that is to say, the genetic variation on which the rest of microevolution rests. The second is natural selection, in which certain genetic variations come to predominate in descendant gene pools on account of the superior fit they consistently provide their bearers to some aspect of the environment. This is the cause of genetic adaptation. The third is genetic drift, in which certain genetic variations come to predominate in the descendant gene pool for nonadaptive reasons, simply blind chance. This would have the strongest effects in small populations, which are of course the kinds of populations that characterize most of human prehistory. For example, a mother who has 10 sons and no daughters will be unrepresented in the next generation's mitochondrial gene pool, while a mother who has only one son and one daughter will be represented; that is to say, the composition of the mtDNA pool is more strongly affected by sex ratio bias than by adaptive selection. The fourth is gene flow, the transformation of gene pools due to interbreeding (or admixture) among members of different communities (Cabana and Clark, 2011). The fifth is inbreeding, mating with genetic relatives, which increases the proportion of homozygotes in a population. If the population includes rare recessive alleles, inbreeding will increase the probability of a single individual inheriting two copies of them. Since we are all to some extent related, all populations are to some extent inbred. Small, circumscribed populations, however, would have higher amounts of genetic drift (randomly elevating the frequencies of rare alleles) and inbreeding (elevating the chances of those recessive alleles being expressed phenotypically).

While in principle the effects of these processes are mathematically distinctive, in practice it is often difficult to distinguish their different effects, except in extreme, rare cases. To establish selection requires not just genetic data but also physiology; to establish founder effect (genetic drift) requires demography. As noted in this article, sickle-cell anemia and thalassemia are solid cases of adaptation, where the selective regime is the endemic threat of malaria; Ellis–van Creveld syndrome in the Pennsylvania Amish and variegated porphyria among the South African Boers are well-established cases of founder effect. Most distinctive genetic variation in human populations lies somewhere in between, such as Tay–Sachs disease in Ashkenazi Jews.

Problems and Prospects

Reconstructions of human prehistory are commonly attempted with genetic data, and are useful for testing hypotheses generated with other kinds of data (Cavalli-Sforza et al., 1994; MacEachern, 2000; Terrell, 2000). The analysis of genetic data often contains hidden assumptions about the demography of ancient populations. Thus, standing alone, genetic conclusions about human history are often model dependent, and may be affected by the strength of selection operating on the DNA sequences being studied; the contractions, expansions, movements, and contacts of the prehistoric populations; the mutation rate; the relationship between the inferred ancestral gene pools and the descendant gene pools being studied; the inferred degree of homogeneity of ancient populations; the inferred modes of evolution (splitting and merging of lineages); and the complex relationship between modern ethnicities (the cultural labels that often guide the sampling process) and ancient gene pools.

The analysis of ancient DNA from human fossils is generating new information on human prehistory and evolution, but to retrieve usable DNA from scarce and damaged human

bones of great antiquity requires extensive precautions against contamination (Hermann and Hummel, 1994). Neanderthal DNA is especially similar to that of living Europeans and Asians, but also different from other archaic human samples (Hofreiter, 2011). We do not know whether the modern human gene pool provides a useful model for understanding the gene pool of our ancestors a few hundred thousand years ago.

Admixture mapping uses carefully chosen polymorphisms that differ significantly across indigenous populations to estimate the degree of relatedness of an unknown sample to each of them. These estimates can then be used to study the heterogeneous ancestry of recently admixed populations. Its applicability is limited, though, for the method uses living populations as proxies for ancestral gene pools, and makes assumptions that are probably unrealistic about the homogeneity (purity) and autochthony (static indigeneity) of ancestral populations.

Genetics and Disaster Victim Identification

Caroline Bennett, University of Kent, Canterbury, Kent, UK

© 2015 Elsevier Ltd. All rights reserved.

Abstract

The use of genetic methods (specifically DNA profiling) is increasingly popular in the identification of disaster victims. Where traditional modes of identification fall short, DNA profiling offers a statistically accurate means of providing positive identification of remains and of reassociating body parts. However, its use is not without problems, including logistical, practical, and social implications. Different cultures have different modes of identification, which may not be scientifically or biologically based, and DNA profiling may conflict with the strict norms and regulations related to treatment of the body after death.

The use of genetics in disaster victim identification (DVI) refers particularly to different methods of DNA profiling; it is one of a suite of methods, often used in conjunction with others, to provide positive, individual identification of human remains following a disaster. A disaster often produces conditions where human remains are degraded, fragmentary, and comingled; as such, the use of DNA is becoming increasingly relied upon to provide authoritative identification in preference over other, traditional, methods such as visual identification, fingerprint analysis, odontological comparison, and osteological analysis.

DNA profiling evolved from the development of other modes of identification, such as the assessment of blood types to determine relatedness, within molecular biology. First commercially available in 1987, the use of DNA profiling as a means of individual identification has developed at a rapid pace over the past few decades. Until recently, it assumed a backseat to other methods of identification, however, due to scientific advances in profiling techniques, combined with increased media coverage and widely publicized successful identification efforts across the globe, and its inclusion in popular media and television shows, it has attained the status among many experts and publics alike as being the ultimate provider of identity. As such it has become almost synonymous with the word 'identification' in the context of DVI; in post-disaster management its use has come to represent responsible, well-ordered, and capable authority; to use DNA analysis in victim identification has become normalized as both a universally appropriate and superior technological intervention. It is therefore often an expected intervention in disaster settings, where many people view identification efforts as central to the process of responsible postdisaster management.

What Is a Disaster?

A disaster is "a sudden, calamitous event that seriously disrupts the functioning of a community or society and causes human, material, and economic or environmental losses that exceed the community's or society's ability to cope using its own resources" (IFRC, 2013). These calamitous events may be natural (such as earthquakes, hurricanes, fires, floods, or other environmentally based events), or of human origin (air disasters or terrorist actions for example), but by definition, they cause events that require external assistance to manage. One of these events is often mass death. Management of the dead is one of the essential actions following a disaster, alongside care for survivors and reestablishment of basic services. It is a crucial aspect of reasserting control and order on a society and people thrown into chaos and disorder by the disaster event. In many (although by no means all) instances, this management includes individual identification of the deceased, and repatriation of the remains. Genetic profiling is becoming an increasingly popular mode of enabling this. Recent examples of disasters that have employed genetic means of identification include 9/11 (2792 deaths); the Asian tsunami of 2004 (over 220 000 deaths); Hurricane Katrina (1836 deaths); the 2009 Victorian bushfires in Australia (173 deaths); and the 2011 Japanese earthquake (over 16 000 deaths).

How Are Genetic Methods Used in DVI?

Whilst the forensic use of genetics is vast, ranging from paternity testing to perpetrator identification, in DVI it is primarily used in two contexts: to provide positive identification of recovered human remains, and to reassociate body parts with one another (to provide as complete a body for identification and repatriation as possible). In the latter case, particularly in disaster situations, the effectiveness of DNA profiling is without comparison as a mode of analysis. In addition, where appropriate, the use of DNA analysis may be used within a disaster to assess perpetrator identification.

The use of DNA profiling enables the matching of one person to another or of one body part to another, through the matching of particular sequences of information within the strands of DNA contained within biological remains. Although all human beings share 99.9% of their genetic information with other members of their species, the remaining 0.1% are unique for every individual (except between monozygotic twins and multiples). It is this variation that enables DNA profiling to be so accurate in its identification (*see* Genetics and Forensics). The specific loci of investigation within the DNA depends upon the method chosen for analysis, and this method depends upon many factors: the aims of the

investigation (identification or body part reassociation for example), the condition of remains, the type of biological material available (teeth, blood, or saliva for example), the environmental conditions of the disaster, and the time elapsed since the disaster.

Despite its reputation as the ultimate provider of identification, DNA profiling is neither a foolproof method of identification, nor is it always successful. Whilst the statistical accuracy of positive identification by DNA analysis is high, conditions must be favorable for a successful match to be made. There must be a reference sample for comparison, either from a close relative, or from belongings of the suspected victim. The remains recovered must be of good enough condition to enable a sample of DNA to be taken; this can depend on the type of remains available (blood, soft tissue, or bone for example), the level of degradation of remains, time lapsed since the disaster (DNA from different materials degrades at different rates – saliva degrades more quickly than blood, which degrades more quickly than bone and so on), and other environmental conditions. In addition, there must be the technical and logistical expertise and facilities, money, and political will to undertake the analysis. This political will depends not only on social norms and values of a given society, but also on the assessed social 'value' of the deceased. Even with the highest level of funding, facilities, expertise, and political will, identification by DNA profiling may not be possible: to date (September 2013) over 40% of the nearly 22 000 pieces of human remains recovered following 9/11 remain unidentified (representing over 1100 victims) (NYC Office of the Chief Medical Examiner, 2013).

Different Types of DNA Profiling in DVI

DNA profiling for genetic identification works by comparing sets of information within certain sections of the DNA to look for a match. Using polymerase chain reaction techniques, laboratories are able to extract and make copies of minute amounts of DNA information that show high variability between populations, or DNA 'markers,' that are useful molecular identifiers. The most common used for identification are short tandem repeat markers, although single nucleotide polymorphism markers may also be used. In DVI cases, the profiling is primarily of DNA markers found either in nuclear DNA or mitochondrial DNA (mtDNA). The relative advantages and disadvantages of either type are outlined in **Table 1**. For a more comprehensive outline of the science of DNA profiling for forensic use, please refer to Zietkiewicz et al. (2012).

There is constant scientific research into new and improved methods of DNA profiling and genetic identification methods (such as the analysis of RNA, next generation genome sequencing); however, these have yet to be useful effectively in a disaster setting.

The Complexities of DVI

Postdisaster management, including identification of the dead, is the responsibility of the country within which it occurs. However, a disaster, by definition, causes events that are either too big or too complex for individual countries to manage

Table 1 Advantages and disadvantages of the profiling of nuclear DNA (nDNA) vs mitochondrial DNA (mtDNA) following a disaster.

	nDNA	*mtDNA*
Cellular location	Nucleus of every human cell except red blood cells.	Cytoplasm of mitochondria – structures within cells that convert energy.
Mode of inheritance	Mendelian	Matrilineal
Advantages in DVI	Mendelian inheritance provides high level of statistical accuracy to identification. Flexibility of analysis methods: can be analyzed using STR markers or SNP markers. High mutation rate of STRs make them highly individualized and ideal for individual discrimination (the statistical probability of one STR frequency matching that of another individual is less than 1 in 1 billion). Low mutation rate of SNPs and their ability to be amplified from minute amounts of DNA makes them ideal in very degraded specimens. SNP analysis exhibits population variability and can therefore be useful in assessing ethnicity.	Matrilineal inheritance means any maternal relative can be used as a reference sample – useful therefore where insufficient information is available within the nucleus, such as very degraded specimens, or where only certain relatives are available for comparison. Less susceptible to degradation from environmental conditions or extraction techniques: Useful in very degraded remains or where only matrilineal identification is needed (e.g., in excluding unrelated individuals.
Disadvantages in DVI	Subject to degradation from environmental conditions or extraction techniques – therefore require well preserved tissue samples and optimal environmental conditions for successful analysis. SNPs can be difficult to assess in mixed samples as is common in disasters. Population variability must be known prior to analysis for accurate profiling.	Less statistically accurate identification due to matrilineal inheritance and cellular location only within the mitochondria.

STR, short tandem report; SNP, single nucleotide polymorphism.
Summarized from Zietkiewicz, E., Witt, M., Daca, P., Zebracka-Gala, J., Goniewicz, M., Jarzab, B., Witt, M., 2012. Current genetic methodologies in the identification of disaster victims and in forensic analysis. Journal of Applied Genetics 53 (1), 41–60.

alone. They are by nature outside the norm and often chaotic, and the management of the dead in such a context is an incredibly complex undertaking. Moreover, in our increasingly connected world, where media are available 24 h a day across the globe, disasters have both a local and global dimension. They become environments with an array of actors operating within them: police, military, government, forensic services, prosecutors, family, survivors, media, and NGOs for example. In addition, disasters often result in complex identification conditions, where bodies are severely damaged, fragmented and degraded by fire, water, or other environmental conditions. Remains of one person may be mixed with those of another, and it is not unknown in manmade disasters such as bombings, for remains of the perpetrators to be mixed with those of the victims. In such conditions, traditional methods of identification such as odontology or visual recognition are often unsuccessful and other methods are therefore required to enable positive identification of human remains. The use of genetic profiling is increasingly relied upon in these difficult circumstances. Where other methods are inconclusive or completely useless, DNA profiling of one form or another can provide some indication as to positive identification of remains.

Against this backdrop, the assumed primacy of genetic modes of identification can be problematic, because of its potential to clash with sociocultural norms and practices. Moreover, its use can cause conflicts within existing systems of power, knowledge, and governance. Often the most catastrophic disasters, particularly natural ones, occur in developing nations; their poor infrastructure and lack of logistical support, expertise, or money to undertake the necessary interventions makes the situation all the more devastating, and they may become reliant on intervening powers who offer support. These intervening authorities may provide consultation on the best way to manage the postdisaster situation, or, in some cases, they may take over its management. In many cases, several organizations will offer support, causing confusion and potential conflicts that invariably compromise effective action.

In these cases, deciding upon appropriate interventions becomes all the more complex. At present no accepted international standards exist on DVI, although many organizations have issued guidelines (e.g., the International Committee of the Red Cross, Interpol, the Pan American Health Organization, the US National Institute of Justice, the Association of Chief Police Officers in the United Kingdom, and many others besides). Although these guidelines mostly conform with one another, they vary in certain details, and the presence of so many different guidelines produces its own problems. Add to that the fact that not all nations necessarily adhere to Western scientific modes of understanding, where identity is biologically expressed through genes, and where individual identification and burial is the most pressing issue in dealing with the dead. The use of DNA profiling in DVI begs questions of place and authority. In particular, the concept of authority and the intervention of external agencies that determine the 'correct' approach to postdisaster management, along with the place of the 'expert' should be questioned, because those considered expert in one world may be very far from it in another place and social landscape.

Why Do We Need to Manage the Dead?

Following a disaster, appropriate management of the dead may become impossible in the struggle to regain control and reestablish stability, particularly where external agencies become involved with their own particular ideas of 'appropriate' postdisaster management. A disaster causes massive disruption in the social fabric of everyday life, throwing communities into chaos and disorder. People often live in a state of stress and panic, both individual and collective, and their lives need to be reordered and their worlds repaired for them to feel secure again. Order must be restored as quickly as possible. A failure to take swift action in managing the disaster invariably causes more problems and can cause further turmoil. The situation in New Orleans following Hurricane Katrina is an example of what happens when immediate action to manage the situation is not taken – moral and social chaos.

For a government or other authority to remain in control it must repair the ruptured cosmos whilst managing the increasingly globalized networks of people involved in the postdisaster management; gaining trust and confidence from its population to do this is imperative to prevent further disorder and chaos. Controlling the treatment of the dead, and effecting identification efforts as early as possible is often central to the process of order reconstruction. Identification of the dead brings them back into the control of the state, through a reassertion of control and order (Wagner, 2008). DNA profiling is an increasingly popular tool in this effort. Its use, or refusal, can support or negate the legitimacy of power and cultural or social ideologies of a society and its governing body; it can consequently be used to reinforce power mechanisms and morality ideals within society (Verdery, 1999). But who decides what kind of management is appropriate and how it should be conducted? And what effect does the choice of DVI by DNA analysis have on the wider community particularly when it is not a native technology?

Critiques of the Use of Genetic Profiling in DVI: Social and Scientific Definitions of Identity

Whilst studies in epigenetics have influenced scientific debates in recent years, encouraging them to explore the complexity of both behavior and identity as multifaceted and neither solely genetically nor solely socially located (see Carey, 2012), lay discourses have yet to embrace these complexities (Prainsack et al., 2014). Western media coverage and public discourse still favors a primarily essentialist notion of identity related to the genes (Dar-Nimrod and Heine, 2011); in this popular discourse, DNA analysis has attained the status of being the ultimate provider of 'truth' and identity for human remains. This is based on the assumption that identity is best assessed biologically. However, this assessment is based on a knowledge system based in Western postenlightenment scientific discourse, which, as with any knowledge system, is itself a product of the sociocultural environment and historical period within which it was born (Finkler, 2000).

Because of these lay beliefs, in the Western world, identification by DNA profiling is viewed as the *only* appropriate means of identification of human remains following a disaster.

Identification by DNA profiling, based solely on physical remains, suggests that identity is inextricably bound to the skeleton and located at the cellular level, and negates identifications produced more socially; through events, or by specific individuals within a community, such as spirit mediums, local healers, doctors, or others who may usually be involved in some places. The conflicts between different systems of knowledge related to identification comes to the fore in DVI when local forms of social identification may be undermined due to the many agencies from differing nations that are often involved. Identities are complexly intertwined presentations of biological, cultural, and social systems, which interact in different ways. How these systems interact and take preference over each other is little understood, and the impact of using one system over another – both on identity and on events beyond the act of identification – is rarely discussed.

The use of genetic profiling in DVI accompanies an assumption that individual identification and repatriation of remains is a central component of the postdisaster management process. Interpol, for example, asserts that identification of remains is 'a basic human right' (Interpol, 2009). Indeed, many people believe it is. However, there exists no directive to this end: neither the UN, nor any other international governing body has established declarations on this issue, and the legal status of remains depends upon the state from which they come. In many societies collective treatment is as legitimate, socially and legally, as individual identification, and even where individual identity is desired, DNA profiling or other genetic means may not be the most socially appropriate technology – other, less statistically accurate, scientifically based, or internationally respected methods may be preferred. In Timor-Leste, for example, identification has been conducted for many years by spirit mediums. The identifications they produce may not be genetically accurate, but they are socially accepted and adhered to. Meanwhile in Cambodia, identity relates not to the skeleton, but to the spirit, and therefore, the actual remains of a person are not necessary for proper funeral rites to be enacted. Over 1 million anonymous remains are scattered across the country following the Khmer Rouge genocide of 1975–79, and cause no social discomfort.

Interventions and assistance are often a necessary part of any postdisaster landscape. Many disasters occur in developing nations, which often lack the infrastructure, expertise, and money, to conduct extensive identification efforts. However, all interventions have social impacts. With DVI there are many questions to be asked of management of the dead, particularly related to identification efforts and specifically genetic identification efforts.

Who has the legal authority over the bodies? Whose dead have priority? Should remains stay within the country or can they be transported elsewhere? How should the dead be stored? How much of a body constitutes a person? Who can manage the dead? What result will improper management have on the dead and the living (e.g., dead intervening in lives of living, etc)? How is identity understood? Who can establish this identity? How does the identity given reflect power and control structures? How does identification by DNA profiling affect, or interfere with, identity by other means? What effect can its prescription have on people? And where identification by DNA undermines traditional modes of identification, and the authority of those who provide it (e.g., monks, spirit mediums, and doctors) how does this affect wider social stability of a locale? What is the actual ability of the managing organization to undertake identification efforts? What result will DNA profiling have in the long term (e.g., on expectations of the people involved)? When do identification efforts end? At what risk is forensic identification enforced at the cost of undermining local social systems and systems of rule? What is the potential effect of undermining these integral structures of stability and order in a society that has already undergone so much disruption and rupture?

Sociocultural Differences in the Treatment of Human Remains and Dead Bodies

The use of genetics in DVI must also be considered in relation to appropriate treatment of the dead. Most societies have strict norms regarding treatment and management of the dead, and breaking these norms can become one of the factors contributing to social unrest. In different cultural situations, belief systems on how the dead are to be treated, and the consequences of ignoring these, vary significantly from Western norms. Following the appropriate norms is imperative in ensuring the fate of the dead; to be able to progress to the next life in Hindu and Buddhism; to ascend to heaven in Christianity; and to lay at peace across the world. In Cambodia, lay ritual specialists work alongside Buddhist monks to free the spirit from the body and allow it to progress through its lives; the physical presence of the corpse is however, not necessary for this to be successful. Religious norms in Muslim and Jewish cultures usually provide that bodies be buried within 24 h, and the body should be buried in as much entirety as possible – the taking of samples for DNA analysis may be of some discomfort in both these cases if the sampling method is destructive (removal of soft flesh, teeth, or pieces of bones, for example). In the Comoros only men can have contact with the dead; in Tibet it is only members of the kin group within which they belong. In cases where (usually Western) experts take samples for DNA analysis, this rule is broken. In parts of Micronesia, to speak someone's name after death brings misfortune to the living (Dernbach, 2005); how then does forensic, individual identification of physical human remains, where the name must be spoken, affect the community in such a case? In most cultures, strict taboos dictate appropriate food, social interactions, and clothing to be used by those managing the dead and for the dead themselves, but it is unlikely DNA identification methods can take these into account in the chaotic and stressful postdisaster environment.

Even the process of identification can be distressing and may conflict with sociocultural norms and expectations. Whilst in some cases taking a sample for DNA profiling from human remains may be straight forward and easily collectible (blood or saliva, for example), due to the calamitous nature of many disasters, taking a sample for DVI may require removal of more substantial parts of the remains, such as pieces of soft flesh, teeth extracted from the head, or pieces of bone sawn from the rest of the skeleton. In such cases taking a sample is a destructive process, involving the removal, and destroying, of (albeit a small) part of the corpse. In some cases, to get at

the bone requires first the removal of the flesh; what then happens to the removed flesh? What implications do these treatments have for people who require as much integrity of the body as possible? When forensic identification efforts of the missing from Saddam Hussein's regime first began in Iraq in 2008, the Iraqi authorities initially attempted to demand that all skeletal samples taken for DNA analysis be returned so that the identified bodies could be buried intact. Of course this was not possible (the bone is ground up in the profiling process), and caused stagnation in the identification process for some years, with the authorities refusing to allow human tissue to leave the country, and yet not having the facilities or expertise to undertake the analysis themselves.

So Why Use DNA Profiling?

The use of DNA profiling in DVI is almost always presented in terms of humanitarian relief and human rights. Individual identification of the dead following a disaster is not, however, an established international human right or legal necessity, and no conventions have yet been created which deem it such. The legal status and rights of the dead vary between jurisdictions and depending on circumstances, and where international conventions do exist on the treatment of mass dead (the Geneva conventions, for example), these relate specifically to the dead resulting from war or conflict.

However, individual, positive identification of the dead may be necessary for many reasons, and not only to provide the assumed closure to family members and societies: establishment of death may be legally required for the production of death certificates, inheritance rights, access to bank accounts, pensions, and other legal actions. Individual identification of the deceased can be necessary to establish those who are still missing. It may be required in order to identify perpetrators. It may be used to give statistical figures for reporting of scale and severity of the disaster, or to provide emotive capital to political statements, which may be used to support international action, even potential military interventions.

In the case of a disaster, DNA profiling is often the most accurate mode of providing these necessary positive identifications. But its increasing use relates not only to its accuracy over other methods, but also to other social mechanisms in play across the globe: local, national and international pressures (real or imagined) that influence action, and the individual and collective benefits that result from undertaking such actions. That which is undertaken under the auspices of being 'for the common good,' or being the 'right' mode of approach, often functions in a much more pragmatic way for those involved (be it postdisaster or in longer term humanitarian aims); it is harnessed as a political tool and as a means of gaining social and cultural capital for all those involved, from individuals conducting the analysis to governments funding it. The use of DNA analysis in the identification of bodies sits within the array of political tools open to manipulation, enabling the harnessing of their symbolic power, the accumulation of social and political capital for those involved in DNA analysis, and, through the handling of these factors, a means of exercising control over a population and acting in the global community.

This is especially true after a disaster, when the social fabric of everyday life is ruptured; not only in the time and place where the event occurred, but in the case of manmade disasters such as terrorist attacks, across the globe as a whole. The very ambiguous nature of bodies – their silence – enables manipulation by one or many voices, and an imbuing of power that cannot be expressed but which is strongly emotive and affective. Their management is therefore paramount postdisaster in order to restore and maintain order following an event that has disrupted life – they possess a form of biopower that can be manipulated by those in authority and provide social and political capital to those involved in their management. By contrast, the disregard of the dead can cause the loss of control and power.

In the increasingly globalized world we live in, our social networks extend beyond our local neighborhoods to include the international community, and the groups with which we engage are ever increasing. Governments and large international organizations participate in these networks too, and are as subject to the social forces at play as are individuals. Disasters that are often entirely localized in their physical effects become globalized in their social impact, and the accumulation of capital, both social and political, affects actions across all these networks. The use of this highly advanced technology is prestigious; both for the individuals involved in taking samples and doing the analysis, and for the agency that undertakes it, or orders it undertaken, or manage its use postdisaster. In many cases it may not really matter whether the technology is used or not, nor its actual success rate. The simple declaration of intention may be enough to both provide social capital and control a chaotic and demanding population.

It is not just the technology that is used in this way. The bodies themselves are also valuable, and can be manipulated as tools of power and capital. Relations with the dead express ideological and moral norms within a society, but they can also expose aspirations (Verdery, 1999). They also have relative worth. The speed with which bodies are collected and identification efforts begin, particularly expensive, technologically advanced techniques such as DNA analysis, indicates the relative value of the dead to the agencies involved: that value often depends on the narrative within which the disaster occurs and how this can be manipulated to gain social capital and political power, both nationally and internationally.

The reality of assistance in international disaster situations is often that governments offer it primarily in order to support the victims of their own country and recover their own dead. This can lead to increasingly difficult situations and conflicts as experts from many nations attempt to recover and identify their dead. It also leads to unequal treatment of the dead from nations who do not have the means or expertise to enact identification efforts even should they wish to. Following the 2004 tsunami in Asia, over 30 international DVI teams worked on identification efforts: teams from Sweden, the United Kingdom, the United States, Spain, France, Germany, Austria, Singapore, and many other nations, worked on recovering and identifying their own dead (Beauthier et al., 2009; Lessig et al., 2006). The number of teams with different modes of working and different priorities led to many issues: bodies went missing, management conflicts caused delays in work, and unequal treatment of the dead was manifested in full sight.

Whilst identification efforts raged for Western victims, the dead from Asia were rapidly buried in mass graves. Identification efforts other than visual means only extended to these dead when the bodies started to decompose, and visual analysis could no longer distinguish identity or ethnicity. Even within the same nation, bodies have relative worth: a comparison of the identification efforts in the United States following 9/11 and Hurricane Katrina illustrate this: identification efforts for the 'national heroes' of 9/11 began within 1 month of the event, and unlimited funds have been pledged to identification, which will continue ad infinitum; in the case of Hurricane Katrina meanwhile, it took over 4 months for the use of DNA analysis to be agreed, and even then only $13 million of funding was provided (Wagner, 2008). The value of the living is also reflected in the treatment of the dead and related identification efforts: the dead of those who are valued are managed in culturally respectful ways; those who are not valued, are not.

Conclusion

The use of genetic modes of identification has become an expected technological intervention in the identification of disaster victims. Where traditional modes of identification fall short, DNA profiling offers a statistically accurate means of providing positive identification of remains and of reassociating body parts. However, its use is not without problems, including logistical, practical, and social implications, and these should be considered in its application.

Genetics and Economic Behavior

Björn Wallace, Faculty of Economics, University of Cambridge, Cambridge, UK

Abstract

This article provides an overview of research on genetics and economic behavior. The field is still in its infancy, but the evidence to date suggests that observed variation in a number of economic behaviors is at least in part due to genetic factors. Despite substantial progress in recent years, more research is needed for a better understanding of how genes influence economic behavior.

Economics and biology have a long history of cross-fertilization. Perhaps most notably from the viewpoint of economics, Thomas Malthus' work on population inspired Charles Darwin's evolutionary theory (Brinley, 1991). More recently, evolutionary game theory has emerged in the intersection between economics and biology (Samuelson, 2002). But, despite this shared heritage, economics has at times lagged behind other disciplines when it comes to incorporating developments in biology. One such area that until recently has been left comparatively unexplored is the relationship between genes and economic behavior.

Like most human behavior, economic decisions – such as, for instance, how much to consume, study, and work or what financial risks to take – are functions of genes as well as environment. As a consequence, they are either directly or indirectly the result of evolutionary processes (Bowles, 1998). Nevertheless, evolution and genes are often overlooked in economic analysis, and while such omissions are often motivated, care has to be taken that important insights are not lost. For instance, ignoring the well-documented influence of genetic factors on education and socioeconomic status could easily lead to erroneous conclusions.

More generally, transmission of economic behavior and outcomes can be either genetic or cultural, and while it may not always matter for analysis and policy, these are by nature different (Cavalli-Sforza and Feldman, 1981; Bowles, 1998). Genetic transmission works from one generation to another, while cultural, that is nongenetic, transmission can occur both from one generation to another, as well as between individuals of the same generation. In addition, cultural transmission can involve more, or fewer, individuals than genetic transmission. Importantly, cultural transmission of behavior has presumably in part evolved as a more flexible complement to genetic transmission which allowed humans to adapt faster and better to complex and variable environments.

While some nineteenth- and early twentieth-century economists like Alfred Marshall drew parallels between economics and biology, it was only in the wake of the nature versus nurture debate in the 1970s that economists started to take a serious look at the influence of genes on economic behavior and outcomes (Witt, 1985; Brinley, 1991; Sacerdote, 2011). This early and important work followed two strands that remain influential to date. The first tried to provide a theoretical and evolutionary basis for the existence, and at times universal fixation, of the assumptions underlying economic models. The second instead studied the influence of genes on variation in economic outcomes. This development in economics mirrored both the more general scientific debate, but also in its focus on intergenerational transmission of economic outcomes and status, the political debate in society (cf Harwood, 1982).

In recent years, the literature on genes and economics has had somewhat of a renaissance. The reasons for this are many, but basically it follows from developments in behavioral economics, evolutionary game theory, and molecular sciences. The latter of these developments has arguably been the most dramatic as it has allowed economists to for the first time directly study the relationship between genes and economic behavior.

Genetics and Economics

Today, we typically think of genes as a segment of DNA associated with a specific function. However, the concept of the gene predates the advent of modern molecular biology and the discovery of DNA. Most work on genetics and economics remain faithful to the original concept and thus define genes as the basic units of biological inheritance. Genes come in different forms and the alternative versions thereof are referred to as alleles. An individual's combination of alleles is his or her genotype and the observable traits of an individual are his or her phenotype. In what follows the general discussion on genetics builds on Neale and Cardon (1992), Falconer and Mackay (1996), and Plomin et al. (2013).

Traditionally, economics has focused on models with no or little heterogeneity, and most key assumptions about the economic agents inhabiting the models are thought to apply universally (Kirman, 1992). Thus, it is hardly surprising that in the wake of the sociobiology debate on the biological and evolutionary influences on human behavior in the mid-1970s, a number of prominent economists suggested that these assumptions could have evolutionary origins (Becker, 1976; Hirshleifer, 1977). Despite an initial flurry of contributions focusing primarily on human altruism, and a series of later articles trying to explain, for instance, preferences for risk taking and timing of consumption, the relevant literature remains small (Witt, 1985; Robson and Samuelson, 2011).

Whereas theoretical work on genes and economics often focuses on universal behaviors, empirical work is by necessity

restricted to behaviors where there is observable variation. The reason for this is simple: in order to identify an association between genes and behavior, we need variation both in phenotype and genotype. We say that a behavior is 'heritable' if variation in phenotype, here economic behaviors can be attributed to variation in genotype. By 'heritability' we thus mean the fraction of variation in phenotype that is attributable to variation in genotype. In genetics it is common to distinguish between broad and narrow sense heritability. The first includes all genetic effects, linear as well as nonlinear, on variation in phenotype, while the second includes only linear, or additive, effects. If the variation in phenotype only depends on variation in one gene, then if the relationship between alleles and phenotype is additive, then so is the relationship between variation in genotype and phenotype. If instead the variation in phenotype is caused by several genes, then we say that variation is polygenic, and additive variation does not only require a linear relationship between alleles and phenotype, but also between genes and phenotype.

Since only additive genetic effects 'breed true' in the sense that the phenotypic effect of genes in offspring is a linear combination of parental genetic contributions, selection and its associated evolutionary processes work primarily on additive genetic effects. It is therefore common to focus on additive genetic effects and often heritability is used simply to denote narrow sense heritability.

That the empirical study of the relationship between genes and economics focuses on the contributions of genes to variation in observed economic behavior or outcomes is an important and often overlooked distinction. Thus, when we say that the heritability of income is 30%, we actually mean that 30% of the observed variation in income in a specific population is attributable to variation in genotype. In other words, an economic behavior that is universal will, by this definition, not be heritable.

Behavioral Genetics

Until recently, most empirical work on genetics and economics used standard behavioral genetic methods. The origins of these can be traced back to the late nineteenth century and the work of Sir Francis Galton. Behavioral genetics studies how genetic and environmental factors contribute to variation in behavioral phenotypes. The approach involves decomposing empirically observed variation into genetic and environmental influences. This is done by studying behaviors or outcomes for individuals of different, but known, degrees of genetic relatedness. For instance, the simplest behavioral genetic studies typically involve either twins or adoptees.

The appeal of twins and adoptees is that these types of family relationships allow us to make assumptions about genetic and environmental correlations. Adopted siblings are typically genetically unrelated, but grow up in the same home, so we can assume that their degree of genetic relatedness is zero, but that the environment is virtually perfectly correlated. In contrast, biological siblings have an expected degree of genetic relatedness of 50% on average, but if they grow up in different homes, then the correlation in environment is likely to be zero. The fact that we know this, allows us to pin down a structural model and decompose observed variation into genetic and nongenetic factors by studying and comparing correlations across the different types of family relationships for the phenotypes of interest. Likewise, twins reared together grow up in the same home, and twins can either be fraternal (dizygotic), in which case their expected degree of genetic relatedness is a half, or they can be identical (monozygotic), in which case their degree of genetic relatedness is one. If we, in addition, assume that there is no assortative mating, no gene–environment interactions, no nonadditive effects, and that environment does not influence identical twins differently compared to same-sex fraternal twins simply because they are identical, then we can calculate (narrow sense) heritability as two times the difference in correlation between identical and fraternal twins.

In psychology, behavioral genetics took off in the 1960s and 1970s, when a number of seminal twin studies established that important traits such as intelligence and personality were heritable. This work was of course supplemented by research on other traits, some of which (like education) were of substantial economic significance. Consequently, by the mid-1970s, the first papers in economics using twins and behavioral genetic techniques were published (Taubman, 1976; Sacerdote, 2011). These papers focused on economic outcomes rather than behaviors and in particular on education and income. In short, the findings were that education and income like other similar traits were moderately heritable, and that shared environment was of limited importance for explaining the observed variation. These early results spurred a fairly large literature, which also came to include adoptees and other types of family relationships, and that more or less confirmed the initial findings of moderate heritability. To begin with, behavioral genetic research in economics focused primarily on the US and used potentially biased samples, but research using data from more representative Northern European samples report similar findings.

Intriguingly, although a fairly substantial literature on the heritability of economic outcomes developed quite quickly along with a very large literature on the heritability of a number of economically relevant traits in psychology, little or no research was done on economic behavior or preferences until fairly recently. The first papers to study actual economic decision-making more directly did not appear until the early 2000s and they tried to estimate the heritability of observed behavior in standard economic experiments, such as the trust, ultimatum bargaining, and dictator games, as well as risk taking (Wallace et al., 2007; Cesarini et al., 2009). Heritability in these experiments was found to be low to moderate and the influences of shared environment small. While the estimates were in line with the preexisting literature on psychological traits, they are typically on the lower end of those observed elsewhere. One potential explanation for this is the comparatively high measurement error associated with eliciting economic preferences (Benjamin et al., 2012a).

The initial experimental papers were followed by a number of papers using survey as well administrative data to study risk taking and investment behavior in the field. Together, these papers demonstrate a low to moderate heritability for a wide range of economic behaviors, preferences as well as

susceptibility to behavioral biases. The most well-studied of these behaviors or preferences is risk taking, which has been studied in the laboratory using incentivized experiments and survey questions, as well as in large sample surveys and using actual real-world investment decisions (Cesarini et al., 2009, 2010; Barnea et al., 2010).

To summarize, the heritability of economically relevant traits is approximately as follows. Intelligence measured by standard psychometric tests is highly heritable, with a heritability of approximately 50–60% (Sacerdote, 2011; Plomin et al., 2013). Education, being in part a function of ability, and personality both have high to moderate heritability of approximately 40–60% (Plomin et al., 2013; Rietveld et al., 2013). Likewise, the heritability of income is about 40% for men, with estimates for women being somewhat lower and estimates using permanent income higher (Benjamin et al., 2012b). The heritability of risk taking in different situations including both experiments and real-life portfolio formation is also approximately 30%, with a range from 20% to 60% (Barnea et al., 2010). In contrast, the heritability of economic behavior observed in other experiments is somewhat lower and are typically around 25%, ranging from 15% to 40% (Cesarini et al., 2009). Finally, the documented heritability of susceptibility to behavioral biases is typically around 20%, but there is variation and zero estimates have been reported (Simonson and Sela, 2011; Cesarini et al., 2012).

Molecular Genetics

Recent developments in molecular biology have made it possible not only to study the contribution of overall genotype to variation in observed phenotypes, but also to study the more direct relationship between actual genes and economic behavior (Beauchamp et al., 2011; Benjamin et al., 2012b; Plomin et al., 2013). Broadly speaking, the research to date has followed two routes. The first is to use available evidence from other disciplines to identify candidate genes. The alternative is to conduct genome-wide association studies using a large number of genetic markers. While the latter type of studies is becoming increasingly popular, they were, until recently, prohibitively expensive and complicated. In addition, when identifying relationships between behavior and individual genes using genome-wide association studies there is the obvious risk of finding spurious relationships.

Candidate genes are typically found by using research in neuroscience as the starting point (Plomin et al., 2013). For instance, it is well known that the dopaminergic system plays an important role in the brain's reward and feedback system. There is also suggestive evidence that genes in the dopaminergic system are associated with novelty seeking and susceptibility to addiction. Consequently, it was suggested already early on that a number of genes related to the dopaminergic system may be associated with economic risk taking and early studies found that this was indeed the case (Dreber et al., 2009; Benjamin et al., 2012b). Similarly, associations were also found between a number of other genes and economic behavior such as that between oxytocin receptors genes and trust.

However, a number of later studies have failed to confirm these initial findings (Benjamin et al., 2012b). Just like the mass significance problem associated with genome-wide association studies, there are a number of problems with candidate gene studies. First of all, there is likely to be a substantial publication bias toward research demonstrating significant relationships between genes and economic outcomes. Secondly, most published studies demonstrating significant relationships, as well as those that failed to find any such relationships, use relatively small samples, often in the hundreds. This means that most studies are statistically underpowered. In fact, it has been argued that the sample sizes typically required to convincingly demonstrate a genetic association to economic behavior under reasonable effect sizes are probably in the tens of thousands rather than in the hundreds.

In this context, it should be noted that economic behavior and outcomes are typically to be considered complex traits involving a large number of different genetic and environmental influences, and that thus far the molecular genetic evidence for complex traits is in some respects rather disappointing (Chabris et al., 2013; Plomin et al., 2013). For instance, both height and intelligence are two highly heritable phenotypes for which there have been a number of genome-wide association studies. However, despite large sample sizes researchers have to date only been able to explain a fraction of heritability in these traits with specific genes. In fact, a recent and very large genome-wide association study on educational outcomes with reasonable power failed to find any substantial relationship between specific genes and education (Rietveld et al., 2013). Education is of course like so many other economic traits a complex trait, but it is also a composite of many underlying and more fundamental complex traits, such as, for instance, intelligence and conscientiousness, complicating matters further.

While the fact that there is no convincing evidence for any large effects of specific genes on economic behavior may at a first blush seem contrary to the behavioral genetic evidence, it is not necessarily so. Evolution has presumably, at least until recently, not selected strongly for economic phenotypes. Rather, these, for instance, active consumers or prudent savers of monetary assets, arise in a modern economic environment. Thus, the economic traits that we are typically interested in are like education composites of other underlying traits that may not even necessarily be correlated. This in turn suggests that rather than being mediated by large effects from a small number of genes, the heritability of economic behaviors may instead be mediated by small effects from a large number of genes (Chabris et al., 2013). In fact, this is what recent studies of complex traits suggest. Instead of studying the effects of specific genes, or using presumed genetic relatedness to infer genetic variation, these studies use genetic variation derived from actual genotypes. But, although such studies cover large parts of the genome, they rarely, if ever, use the complete genotypes of the sampled individuals. Therefore, the heritability estimates derived from these types of studies can arguably be considered lower bounds (Benjamin et al., 2012a; Rietveld et al., 2013). For economic traits the estimates for survey-based preferences range from 0% (fairness) to 34% (economic policy), while the average estimate for education is 24%. The fact that several of these estimates are significant strongly suggests that economic behaviors and outcomes are under genetic influence.

Broadening the Discussion

Some 40 years of research on genes and economics has demonstrated that economic outcomes such as education and income are in part heritable. The more recent literature on the relationship between genes and economic behavior is still in its infancy, but the evidence so far suggests that this is mostly likely also true, albeit to a lesser extent, for a number of key economic behaviors and preferences. While most research in the field supports the conclusion that economic traits are under genetic influence there are several reasons to be careful in interpreting the literature. One important reason for this is that a substantial share of the literature relies on data from twins, and some of the assumptions underlying the behavioral genetic models using twins are controversial. In particular, the assumption that same-sex fraternal and identical twins are not influenced differently by environmental factors due to their different genetic relationships with their co-twins has attracted a lot of criticism. Furthermore, the literature struggles with separating additive from nonadditive genetic effects as well as with accounting for interactions between genes and environments more generally.

However, based on the evidence from the extensive nature versus nurture debate on intelligence it is reasonable to assume that while the criticism against twin models is in part motivated, the qualitative finding that genes influence economic behaviors and that these are heritable is likely to be unchanged by future research. This conclusion is supported by the recent genome-wide association studies that were able to link variation in economic behavior and outcomes to actual genetic variation on the molecular level. Thus, as far as we can tell economic behavior is under genetic influence. As a consequence, the key problem arguably becomes not if genes influence economic behaviors, but rather to what extent and what the implications are. Empirically, more large scale traditional behavioral genetic and genome-wide association studies are needed for a better understanding of the heritability of various economic behaviors and the interaction between genes and environment. Perhaps more importantly, empirical research needs to be complemented by theoretical research and be better related to theory. On a fundamental level, common misunderstandings hamper research on genes and behavior. The perhaps most important of these is that if a trait is heritable, then it is immutable. That this is not so can easily be seen by considering the heritable traits myopia or religion. Likewise, not all economic behaviors are as likely as others to be under genetic control or to be heritable. Here, evolutionary and anthropological theory and evidence can help to guide research both on the planning and analysis stage. In addition, models that incorporate both heterogeneous agents and modes of transmission are presumably needed to better understand the implications of heritability of economic behavior.

Abstract

This article provides an overview of the use of genetic science and technologies for criminal investigation and forensics. After discussing the history of the use of biological markers for criminal identification and forensics, we outline the emergence of DNA analysis as the 'gold standard' in forensic identification. We then discuss a range of more recent practices and issues in the field of forensic genetics. We conclude with a brief discussion of novel technologies that have not yet found entrance into most courtrooms and routine crime scene work.

Background: Forensic Identification

In criminal investigation, it often is useful to try to link bodily traces to suspect bodies, which may have been present at sites of interest or had contact with persons or objects of interest. The earliest uses of such traces probably involved handwriting, but the paradigmatic forensic identifier is the fingerprint, which came into regular use for forensic purposes in the early twentieth century. Unlike handwriting, which is a volitional act, fingerprints are bodily attributes, which are in some sense outside the control of the individual, and which we call *markers*. Other forensic identification marker sources included hair, dentition, and blood. The foundation of bodily forensic identification lies in the claim that traces can, with some degree of accuracy and precision, be linked to the suspect body. A 'known' fingerprint trace is compelled from the suspect body (i.e., by 'rolling' the suspect's fingerprint), and the 'known' and 'unknown' traces are compared. For most of the twentieth century, fingerprinting often was called the 'gold standard' in forensic identification and, indeed, forensic science more generally. Fingerprints were particularly useful for forensic science for a number of reasons: People generally deposited fingerprints fairly prolifically, making the recovery rate high, despite rather well-known and easily adopted countermeasures like wearing gloves. Whereas handwriting identification may have been particularly useful in investigation of crimes like fraud and other financial crimes involving documents, fingerprints were deposited by the anatomical organs of touch, which were frequently employed in the commission of crimes, especially violence and theft. Fingerprints could be compelled from suspects easily and cheaply. These known prints could be indexed according to their 'pattern types' by trained classifiers and could be stored relatively cheaply. At the same time, however, the utility of fingerprinting was limited. Not all crime scenes yielded incriminating prints. If suspects were not identified by investigative means, the examiner would have no 'known' to which to compare the crime-scene print. The database could be consulted, but this often was prohibitively difficult because most databases were indexed according to the pattern types on all 10 fingers, whereas crimes scenes rarely yielded complete sets of 10 prints. This issue placed severe limits on the utility of fingerprint databases in suspectless crimes until the flourishing of computerized searching in the 1980s.

Development of Forensic DNA Profiling

Forensic serology, the analysis of blood, was not new. It had been possible for decades to analyze blood stains for blood type and also for the presence of various enzymes. These tests, however, were not sufficiently discriminating. Serology was mostly helpful for the exclusion of suspects (e.g., if a trace that must have come from the perpetrator had a different blood type than the suspect). Fingerprinting, at this time, was claiming to be able to achieve infinite discrimination, that is, to the level of a single individual (this claim later was found to be unfounded). With criminal investigation paying increasing attention to biological information, the utility of treating genetic information as a forensic marker was clear. It was in this milieu that the utility of Alec Jeffreys' discovery of probes for visualizing variable-number tandem repeats (VNTRs) (*see* Forensic Genetic Databases: Ethical and Social Dimensions) for forensic identification gradually became apparent. Given a sample of bodily fluid, the forensic investigator could posit the same sort of link between a bodily trace and a suspect body that had been posited for fingerprints. Indeed, Jeffreys called the technique 'DNA fingerprinting' in a deliberate evocation of the older technique (Lynch et al., 2008). Because DNA profiling – the term that later became standard – targeted a different type of bodily trace than fingerprint analysis did, it could be used in investigations in which no usable fingerprints were found, but in which body fluids from the likely perpetrator were present.

Briefly, Jeffreys' method utilized the fact that human beings have different variants of DNA in certain places on their chromosomes; in healthy individuals, DNA is the same in every cell in the body. The higher the number of places (loci) in the chromosome that are being analyzed, the smaller is the likelihood that two individuals have the same DNA variants in all the same places (unless they are identical twins or multiples; for more details, *see* Forensic Genetic Databases: Ethical and Social Dimensions). Jeffreys' method of DNA analysis went far beyond serology in the sense that it allowed for the testing of several genetic loci, which offered much higher discrimination in the analysis of bodily fluids. The technique was famously first put to use in 1986 in a serial rape-murder cases in Narborough in the United Kingdom near Jeffreys' laboratory at the University of Leicester. There was a prime suspect, who even confessed to the crimes; genetic analysis, however, excluded him as a possible

perpetrator. The police then conducted what later would be called a 'DNA dragnet,' demanding blood samples from every eligible male in the area. This pressure eventually flushed out a witness who reported that a suspicious colleague was seeking to evade giving a sample. Several themes that would become important for genetics and forensics, including the exoneration of the innocent, DNA dragnets, and the power of the perception of the technique's accuracy to flush out other kinds of evidence (e.g., Machado and Prainsack, 2012), were presaged in this case.

The technique's potential for forensics was apprehended relatively quickly, and some law enforcement agencies, including the (now defunct) UK Forensic Science Service (FSS) and the US Federal Bureau of Investigation (FBI) moved quickly to develop it. In addition, a number of private companies arose to market the DNA profiling services (Daemmrich, 1998). The technology developed rapidly. Systems based on the polymerase chain reaction (PCR) were developed during the 1990s. These systems enabled 'amplification' of forensic traces – small amounts of genetic material could be copied until sufficient material to test was available, and testing also became faster. But early PCR markers lacked the discrimination of Jeffreys' original technique. The technique of counting short tandem repeats (STRs) – repetitions of chains of nucleotides in given loci – combined PCR's amplification capability with high discrimination power. STR-based techniques remain the most common DNA profiling system used in criminal justice. According to the latest survey carried out by Interpol on this topic, 120 of the 172 Interpol member countries reported to have used DNA profiling (Interpol, 2008).

Effects on Criminal Investigations

The effect of genetics on criminal investigation may usefully be divided into two categories: cases in which genetic analysis inculpates a suspect and cases in which it exculpates a suspect or convict. There is, obviously, a quite significant third category of cases in which genetic analysis neither inculpates nor exculpates. Examples of such cases might include those in which the genetic samples are degraded, contaminated, or otherwise not fully analyzable a relatively robust profile is not linked to a person of interest in solving the crime, or the DNA profile of the suspect could have ended up at the crime scene for legitimate reasons (see following section).

Inculpation

Genetic analysis is of obvious utility in providing inculpatory evidence in the investigation of crimes. Evidence of a possible common source between a crime scene sample and a sample from a known individual can provide strong evidence of that individual's presence at the crime scene. Depending on the nature of the sample, that evidence may be more or less incriminating in the actual commission of the crime. For instance, consistency with a genetic sample derived from a semen sample from a rape-murder case may be incriminating. On the other hand, consistency with a genetic sample derived from a sweat stain at a public, highly trafficked location may be far less incriminating. Incriminating links need not necessarily involve a crime scene. For example, links might be drawn between a genetic sample recovered from a suspect's property and a genetic sample known to come from the crime victim.

Although it is commonplace to speak of genetic 'matches' in forensics, in fact, an association between two genetic samples is probabilistic in nature. Genetic forensic scientists assess whether the two samples appear to have the same alleles at the designated loci. This assessment sometimes can require interpretation, as when there are ambiguities as to whether a given result is genuine or is the result of noise, contamination, mixture with DNA from another source, and so on. Even if the findings of consistency are assumed to have been interpreted correctly, however, a further question concerns whether other individuals in the population might have the same array of alleles at the designated loci. A monozygotic (identical) twin is an obvious possibility. Even setting twins or multiples aside, however, genetically distinct individuals might by chance have the same array of alleles at the loci examined. It is, therefore, necessary to try to estimate the rarity of the array of alleles. A common such estimate used in forensics is a 'random match probability' (RMP). Genetic information has an unusual data structure not shared by most other forensic disciplines – the alleles are numbers of repeats and thus exist in nature as discrete whole-number values, rather than continuous measures – which makes the calculation of such estimates relatively straightforward in simple (e.g., nonmixture) cases.

It is necessary to take this estimate into account when considering the inculpatory value of a finding of genetic consistency between two samples. Many forensic scholars believe strongly that the proper framework for such considerations is what generally is known as a 'logical' or 'Bayesian' approach based on a likelihood ratio, but the penetration of this approach into routine practice and courtroom proceedings has been mixed. The approach has been embraced in some countries such as the Netherlands and Sweden, and it was strongly promoted by the FSS in the United Kingdom. In other countries, like the United States, however, the Bayesian approach remains rare. Instead, most forensic genetic expert witnesses testify about RMPs. In some cases, when RMPs are low, experts testify, controversially, to source attributions – that is, a single individual *is* the source of the forensic trace.

One paradox of advancing technology is that, as genetic tests have become increasingly sensitive, their incriminating value is in some cases beginning to erode. In the earliest days of genetics and forensics, blood or semen were necessary to contain sufficient genetic material to analyze. This left a lot of crime scenes impervious to genetic forensics, but if an association between a suspect and a blood or semen sample was established, that association often was quite difficult for the suspect to explain away without reference to increasingly fanciful scenarios involving other attackers or other less probable events. Contemporary technology, however, is capable of recovering analyzable samples from quite small traces of genetic material derived from sweat, hair, skin cells, body oils, and so on – so-called 'touch DNA.' This makes genetic analysis deployable for a much broader variety of crimes from auto thefts to financial crimes. At the same time, it increases greatly the number of samples that will be recovered from a particular crime of object, but it also increases the probability that the

sample came to be at the scene 'innocently' through a prior visit or transfer, thus increasing the range and plausibility of defense that might explain a finding of association. Planting scenarios are also increasingly plausible.

Exculpation

Many exculpations, presumably, occur at the investigative state. How many is not well understood, although during the early years of DNA profiling, the FBI reported that around one-quarter of prime suspects were exculpated by DNA analysis (Connors et al., 1996). The more spectacular exculpations are those that have occurred postconviction. Because biological evidence is sometimes preserved, the development of genetic forensics in the 1980s made it possible to retest evidence postconviction. This resulted in a significant number of spectacular exonerations of individuals who often had served long prison sentences, under sentence of death in some cases, for crimes they apparently did not commit. The primary locus of such exonerations has been the United States, possibly because of better preservation of evidence, where there have been more than 300 'post-conviction DNA exonerations' since 1989 (Garrett, 2011). Although there always have been other means of exonerating the convicted – and, indeed, during the period since 1989, there have been more non-DNA exonerations than DNA exonerations – DNA exonerations have an ability to achieve 'epistemological closure' (Aronson and Cole, 2009) that other exonerations usually lack. This means that 'innocence skeptics' are less disposed to challenge the factual basis of exonerations when they are vouched for by genetic evidence. In most cases, such challenges rely on changing the government's theory of the crime from single- to multiple-perpetrator rape. In recent years, initiatives of lawyers working *pro bono* to exonerate the wrongfully convicted have become more widespread in countries outside of the United States, including Canada, France, New Zealand, and Australia.

In the United States, the wave of DNA exonerations has been extremely influential in stimulating the movement for criminal justice system reform and also for supporting opposition to capital punishment. Seemingly paradoxically, a small number of the US DNA exonerations have involved individuals who also were convicted on the basis of genetic evidence, evidence that was either misinterpreted or presented in a misleading manner (Garrett, 2011). It has long been predicted that DNA exonerations eventually would wane, as DNA testing at the investigation stage became routine, but thus far exonerations continue.

Use as Evidence in Court

The 'DNA Wars'

During the earliest years in which DNA evidence was introduced, its admissibility was extensively litigated in the United States, in a series of contests sometimes labeled as the 'DNA wars' (Aronson, 2007; Kaye, 2010) and in the United Kingdom (Lynch et al., 2008). In the earliest US cases (in the late 1980s and very early 1990s), DNA evidence was either not challenged or not challenged expertly, and it was routinely admitted. In later cases, however, defense attorneys enlisted well-credentialed molecular biologists who were able to gradually expose sloppy practices, failure to adhere to protocols, and unprincipled (and biased) interpretations of data. These interventions and criticisms produced a few cases in which state courts excluded DNA results, perhaps most famously in *People v. Castro*. Not insignificantly, these exclusions quickly were followed by federal courts deeming similar evidence admissible. The courts also exercised caution in early cases in the United Kingdom and Australia (Edmond et al., 2013). In the United Kingdom, proposals to employ Bayesian statistical analysis to interpret DNA evidence were rejected by the courts (Lynch et al., 2008).

Successful challenges to the admissibility of DNA evidence in the United States drew on population genetics to challenge calculations of RMPs. Drawing on debates among geneticists about human mating patterns, defendants argued that the state's RMP calculations were not accepted in the scientific community. These cases helped to trigger the intervention of the US National Academy of Sciences – through its National Research Council (NRC) committees. The NRC issued two reports, in 1992 and 1996, each of which endorsed two different ways of estimating the RMP, the 'ceiling principle' and the 'product rule,' respectively. Following the first report, some courts excluded RMPs proffered by the government. The second report, however, practically eliminated admissibility challenges based on population genetics; to the extent that the government asserted that it was adhering to the NRC recommendation, admissibility challenges were unlikely to succeed, and subsequent cases upheld admissibility. Since the mid-1990s, DNA evidence in general has been universally admissible in the United States and many other countries (Edmond et al., 2013; Hindmarsh and Prainsack, 2010). Another consequence of these reports was that the issue of accounting for human mating patterns was resolved by allowing for the calculation of RMPs based on gross categories labeled 'race' (Kahn, 2008): for example, in the United States the categories were 'White,' 'Black,' and 'Hispanic'; in the United Kingdom, they were 'White,' 'Black,' and 'Asian.'

Perhaps the most famous motion to exclude DNA evidence was one that was never filed. Although the defendant's 'dream team' prepared an extensive motion to exclude DNA evidence in *People v. O.J. Simpson*, sometimes called 'the trial of the century,' they withdrew the motion early in 1995. Instead, the defense team famously – and generally, it would appear, successfully – opted to attack the weight of the evidence at trial by alleging sloppy procedures, inadvertent contamination, and possible planting of evidence (Aronson, 2007: p. 173; Kaye, 2010: p. 152).

Targeted admissibility challenges still are made. One avenue of challenge concerns how a 'cold' database search affects the calculation of the RMP. Because statisticians disagreed about how the fact that a DNA association was generated through a database search should be handled (although all agreed that it mattered), some defendants argued, unsuccessfully, that the government's method of calculating the RMP was not 'generally accepted.' There has been some litigation on statistical grounds about the conclusions that DNA analysts should be permitted to state in their testimony and that prosecutors

should be permitted to state in their summations. There has thus far been only a small amount of litigation over DNA profiling techniques more exotic than the STR testing that has become standard. The admissibility of Y-STR haplotyping (the analysis of DNA in the male sex chromosome, which can provide information on paternal lineage) and mitochondrial DNA profiling (i.e., the analysis of DNA that is not contained in the nucleus of the cell; mitochondrial DNA is passed on from mothers to children) both have been upheld in the United States (Kaye, 2010). In England, Wales, and Australia, there has been litigation concerning low-copy-number (LCN) DNA profiling (Gilder et al., 2009). LCN DNA profiling is a particularly sensitive method of analysis for which only tiny amounts of DNA – a few cells – are needed. Disagreement remains about the reliability of LCN DNA markers.

As the technology has improved and RMPs – that is, the chances that a DNA profile obtained from a crime scene matches the profile of a randomly drawn profile from the general population – have gotten smaller, the arguments for the importance of race and racial mating patterns have diminished. It originally was argued that race-specific calculations of RMP were important to generate more accurate RMPs, but some social scientists now argue that the purported accuracy gains derived from using racial categories 'fade into irrelevance' and are outweighted by the harms of reifying crude notions of genetic races (Kahn, 2008).

Effects on Forensic Technologies

Although the legal admissibility battles generally have resulted in admissibility for genetic forensics, they had unexpected and unintended consequences for other areas of forensic science. The sophisticated disputes involving high-powered scientists over population genetics and the statistical reporting of results provoked the question of how these issues were addressed in other areas of forensic identification, such as fingerprinting, firearms and toolmarks, bitemarks, handwriting, microscopic hair comparison, and so on. It turned out that all these fields had been indifferent to statistics, viewing it as unnecessary to seek to statistically characterize the size of the potential donor pool of forensic traces. Instead, these fields had relied on semantic workarounds that evaded these issues, and courts, historically, had permitted them to do so. The admission of genetic forensics into court thus had the effect of prompting defendants and scholars to demand that these older fields of forensic science account for themselves probabilistically, resulting in admissibility challenges to venerable techniques whose admissibility had seemed long settled. These developments have lent momentum to a movement toward probabilistic thinking in forensic science, which has held that all evidence can, and should, be understood probabilistically. It also generated a phenomenon that has been called an 'inversion of credibility' in which genetic forensics, which in the early 1990s routinely described itself as similar to, but weaker than, venerable techniques like fingerprinting, came to be widely seen as stronger. The period in which proponents of genetic forensics sought to bolster their credibility by invoking analogies with fingerprinting was followed by a period in which genetics was widely seen as having succeeded fingerprinting as the 'gold standard' in forensics (Lynch et al., 2008).

The 'CSI Effect'

Another potential unintended consequence of the development of DNA profiling is the so-called CSI effect, a term used somewhat inconsistently to mean a variety of things. Increasing awareness of the existence of forensic genetics may reasonably be expected to have a legitimate effect on the behavior of various criminal justice system actors, including attorneys, judges, jurors, police, and offenders. This effect has been dubbed the 'tech effect' to distinguish it from the 'CSI effect,' which generally is used to denote an exaggerated, and often false, belief in the power and capabilities of forensic science, including forensic genetics, fostered by popular fictional media, especially television programming. The most common claims have been advanced in regard to US juries, which, it is claimed, are acquitting in cases in which they would have convicted but for television programming. Evidence in support of such strong claims of a 'CSI effect' is thus far weak, but claims of changes in attorney, offender, or even individual juror behavior are better supported (Shelton et al., 2006; Cole and Dioso-Villa, 2007; Machado and Prainsack, 2012; Cole, in press).

Databases

In the early years, the results of DNA analysis from crime scene and suspect samples were compared in an ad hoc manner – that is, in the context of specific investigations and trials – and stored in a decentralized manner, if they were stored at all. In the mid-late 1990s, as an effect of both the increasing importance of STR-based DNA analysis in forensic investigation, and in court, centralized databases for police and forensic use were set up in many countries. The ways in which these databases were set up differ greatly in terms of when they were started, what the criteria for inclusion and expungement of profiles are, and in whose custody the database is held (*see* Forensic Genetic Databases: Ethical and Social Dimensions; see also Hindmarsh and Prainsack, 2010; Krimsky and Simoncelli, 2011). Not all countries had or have dedicated laws governing the establishment, maintenance, and use of DNA databases. What all DNA databases for police and forensic uses have in common, however, is that they include DNA profiles from crime scenes and from convicted offenders; some databases store profiles of suspects (e.g., England and Wales) or volunteers (e.g., Portugal) as well.

All databases allow so-called speculative searching, which means that profiles obtained from crime scene stains, or from subjects, can be compared against all other profiles in the database, without there being a particular suspect, or a hypothesis regarding how specific profiles could be linked. By making speculative searching possible, centralized DNA databases have given rise to many new 'cold case' investigations, that is, the reopening of investigations of cases that had ran out of leads (Innes and Clarke, 2009). At the same time, speculative searching has led to concerns about false matches within the database. This is particularly relevant in the context of very large databases, or networks of databases, such as the Prüm network: The Prüm network is based on EU law that obliges member states to render their DNA databases searchable to each other (at a hit–no hit basis; supposed profile matches then are followed up bilaterally by the countries between which the databases matches were

obtained; see Prainsack and Toom, 2013). In 2011, databases within the Prüm network included more than 9 million profiles (ENFSI, 2011); comparing all these profiles with each other would lead to several trillions of DNA comparisons. This means that, depending on how many loci are searched, even with very low RMPs (e.g., several billions), numerous false matches could result from every single search within the database. It is also for this reason that the European Union has endorsed the inclusion of five new markers in the European Standard Set of Loci (ESSOL; a voluntary agreement on a minimum set of genetic loci that DNA analysis in all countries include, irrespective of what chip and software they use for analysis; see Gill et al., 2006; European Union (EU) Council, 2009). These five markers will be added to the Combined DNA Index System (CODIS) used in the United States and elsewhere to ensure compatibility of DNA profiles across countries also outside of Europe, and within the DNA Gateway run by Interpol (*see* Forensic Genetic Databases: Ethical and Social Dimensions).

Function Creep

Over the course of the development of genetic forensics, the functions and uses of some DNA databases have expanded beyond those originally intended. This phenomenon has been referred to as function creep (Dahl and Sætnan, 2009). For example, the fact that biologically related people share more genetic markers in common than unrelated people could be used to search for biological relatives of a person in connection with a crime in the DNA database. Another example is the increasing use of genetic information to generate 'intelligence' about hitherto unknown crimes or linkages between crimes (Ribaux et al., 2010). Still another example is the linkage of DNA analysis results carried out by handheld devices with DNA databases. This may emerge as a result of the development of ultrarapid (i.e., a few hours) DNA analysis that does not need to be carried out in a laboratory but can be performed by crime scene officers, and analyses could be compared automatically against profiles held in the database (currently, this is not done in any country). Such a scenario would raise questions about accreditation, and about data leakage and misuse, and about the exacerbation of biases against certain population groups if handheld DNA analysis devices also would be used in police patrols. A third example is the storage of so-called single-nucleotide polymorphisms (SNP)-data or Y-chromosome STR data, alongside conventional STR-profiles in centralized DNA databases. SNPs are variations at the level of single nucleotides (G, A, T, C); forensic SNP-based tests scan places across the entire genome for such variants and highlight those that have been found to correlate with particular physical traits (e.g., eye color) or ethnicity in scientific studies (e.g., Kayser and Schneider, 2009). The question about storage of SNP-data thus emerges in connection with phenotypic profiling. Y-chromosome analysis, which can give clues about paternal lineage and – in societies where surnames are patrilineal – allow probabilistic inferences about a person's family name, has been used in criminal investigation for decades; however, the results of Y-chromosome analysis are not stored routinely in centralized DNA databases and thus are not regularly available for speculative searches. There is a Y-chromosome haplotype reference database that can aid case workers by providing Y-STR haplotype frequency estimates, but this database does not contain profiles of particular convicted individuals.

Access for Researchers

There is great variety between jurisdictions as to whether or not they allow researchers to access DNA samples or profiles stored in the database. Any research carried out with these materials or data normally will have gone through institutional research ethics reviews, and personal identifiers (names, addresses, etc.) will not be disclosed to researchers, although recent studies have shown that anonymization is no guarantee that reidentification will be impossible (Gymrek et al., 2013). The STR-based DNA profiles currently stored in centralized DNA databases are not useful for sensitive research into, for example, correlations between genetic markers and antisocial or criminal behavior, intelligence, disease propensity, character traits, sexuality, and ethnicity. This is because STR profiles – which are stored as strings of numbers in the database – represent random genetic variants of which we have millions, most with yet unexplored, or nonexisting, function. DNA *samples* – the physical material, such as blood or saliva stains, from which DNA profiles are derived – are stored in the laboratories carrying out the analysis in some countries, while other countries require that labs destroy samples once the DNA profile has been obtained. Retained DNA samples potentially could be useful for such future research, as would the analysis of existing SNP data (see next section on phenotypic profiling). In addition, some scholars have called for database custodians to allow increased access to (purportedly) anonymized data to better facilitate research on issues related to forensics, such as, for example, the statistical independence of the alleles used for profiling (Krane et al., 2009). Paradoxically for some, database custodians have emerged as defenders of the personal privacy of convicted offenders in these debates. The use of DNA samples and data collected and generated during criminal investigation for research raises a range of political and ethical concerns, especially in cases in which no transparent and publicly accessible information about the purposes and terms of such research exists.

Surreptitious Sampling

Concerns have been raised also about the practice of so-called surreptitious sampling. In the context of forensic genetics, the term 'surreptitious sampling' refers to analyses carried out on DNA that has not been obtained with the knowledge of the originator (the 'owner' of the DNA). Surreptitious sampling could use DNA left behind by suspects on coffee mugs, chewing gum, cigarette ends, or clothes, for example (Joh, 2006). At present, DNA profiles obtained by means of surreptitious sampling cannot be uploaded to the DNA database in most countries; they can be used only for comparisons in concrete cases, if at all. The issues around surreptitious sampling – or better, 'convenience' sampling in this context – would become pressing if portable DNA testing devices were deployed locally (e.g., at police stations or on police patrols), and if the people operating the device could compare the profile generated by the portable device with the profiles stored in the national database. This could lead to a situation in which individuals from whom it is not legal to demand a DNA sample could be submitted to

testing 'through the backdoor.' Moreover, as members of ethnic minorities are more likely to be affected by routine police controls in many countries ('racial profiling'), this practice also would exacerbate existing ethnic and racial biases.

Phenotypic Profiling

Another, more recent, practice that is sometimes discussed in connection with racial profiling so-called phenotypic profiling. Conventional, STR-based forensic DNA profiling looks only at genetic markers that do not allow for any meaningful inferences regarding a person's externally visible traits, such as her hair or eye color. If different markers on the genome are analyzed, however – namely, those that have been found to correlate with externally visible traits (Keating et al., 2012) – then inferences can be made regarding the person's likely characteristics. These inferences always will be probabilistic, because the predictive power of the genetic markers regarding expressed phenotypic traits is limited. In principle, this method can be highly useful in the context of some criminal investigations – for example, if there are no known suspects, phenotypic profiling could give an indication of what the perpetrator could look like and also what ethnic background she or he is likely to have. The latter is the case because some of the same markers that correlate with externally visible traits are typical for specific population groups. This example illustrates both the potential benefits as well as the potential risks inherent in phenotypic profiling (M'charek, 2008). Because the information obtained by this method is, as mentioned, not deterministic but probabilistic, its utility is limited, not only as evidence at court, but also as intelligence in a criminal investigation. For example, if in the context of a dragnet, the information that the perpetrator is 67% likely to have blue eyes, were used to target only people with blue eyes, the real perpetrator could be missed. (As dragnets are highly intrusive for those asked to volunteer a DNA sample, there is wide agreement among experts that they should be used sparingly, and only in a range of narrowly defined contexts; see Zadok et al., 2010.) DNA information used for phenotypic profiling purposes currently is not stored routinely in centralized DNA databases. Phenotypic profiling could be useful particularly in narrowing down the range of missing persons to which unidentified bodies could be matched (also in the context of disaster victim identification).

Familial Searching

'Familial searching' – which arguably would be more accurately called 'genetic proximity testing,' as not all genetically related people feel part of a family, and vice versa – can be performed if a DNA profile derived from a crime scene stain results in a partial match with a profile in the database. For example, two profiles might not match in all of the analyzed genetic loci but in most of them (e.g., in 11 of the 13 loci used in the US Federal CODIS database; for this reason, some authors call it 'low stringency,' 'near-miss matching,' or 'kinship matching'; e.g., Kaye, in press). The 'hit' in the database could have identified a genetic relative of the person who actually left the DNA at the crime scene. Police could then investigate whether the person identified has any biological relatives who could have committed the crime. In the United Kingdom and in the United States, for example, several cases have been solved by this method. In other countries, genetic proximity testing is explicitly or implicitly forbidden. Critics of genetic proximity testing argue that this method violates the privacy of the person whose profile has been identified on the database through the matching attempt, as well as the genetic privacy of the (genetic) relatives of the person whose DNA profile has been identified, and that it could reinforce the stereotype of 'crime running in families.' Moreover, some critics are concerned that a criminal investigation using genetic proximity testing could reveal a genetic link (or lack thereof) between members of a family that they currently were unaware of (Haimes, 2006, see also Greely et al., 2006). Finally, genetic proximity testing is seen to repeat existing demographic and ethnic biases within criminal justice systems. For example, in the forensic DNA database for England and Wales, black individuals are clearly overrepresented: According to the 2011 census in England and Wales, about 3.5% of those who filled in the questions about ethnicity self-identified as 'black' (in addition, just over 1% were of 'mixed' ethnicity, including 'black'; Office for National Statistics, 2011). The proportion of DNA profiles from 'black' individuals stored in the National DNA Database (NDNAD) is currently at more than 8%, that is, almost exactly double the proportion of black individuals in the general population (National Policing Improvement Agency, 2012). Although no data are available regarding socioeconomic background in this respect, a similar overrepresentation of certain groups is a possible, if not likely, scenario. This, in turn, means that individuals genetically related to people whose DNA profiles are stored in the database have a higher risk of being the subject of an investigation than genetic relatives of individuals whose profiles are not in the database, which raises questions about equity and fairness.

Future Prospects: Gene Expression and Microbiome Analysis

A limitation of the use of any kind of DNA analysis for forensic identification purposes is that it is impossible to differentiate monozygotic twins or multiples with this method. At least two strands of current research could provide solutions for this: The first is the comparison of gene expression profiles that do not look at the sequence of nucleotides but rather at what genes are expressed. Although monozygotic twins and multiples – who have developed out of one single egg and sperm – carry the same nucleotide sequences in their genes, this does not mean that all of these genes are *expressed* in the same manner. Lifestyle, environmental exposures, and other factors have the potential to switch certain genes 'on' or 'off' epigenetically without altering their structure. Epigenetic modifications – such as DNA methylation, that is, the addition of a methyl group to a DNA nucleotide – affect how genes are transcribed and expressed (see e.g., Bell and Spector, 2011; Li et al., in press). Another way of distinguishing people who carry identical DNA sequences is looking at the microbes they carry in their bodies, for example, in their throat. 'Throat-swabs' disclosing the composition of microbes could complement the traditional buccal swabs, in which cells are taken from the inside of the mouth to isolate DNA. It is unlikely that microbiome profiles will ever replace DNA profiles, however, because

they have the disadvantage that they are not stable – the composition of microbes changes over people's lifetime. For concrete investigations, however, micobiome profiles could distinguish people with identical DNA profiles in the future.

Genetics and Indigenous Communities: Ethical Issues

Emma E Kowal, University of Melbourne, VIC, Australia

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Indigenous people stand to benefit from advances in genomic technology, but genetic research in Indigenous communities has been controversial. This article reviews the ethical issues that Indigenous people and others have raised with reference to genetic research projects and biobanks. The ethical issues that apply to Indigenous people should be seen as additional to 'conventional' ethical issues that apply to all people, rather than replacing them. The additional ethical concerns discussed include group harm; cultural beliefs relating to biospecimens and human origins; community engagement and collective consent; benefit; ownership; and whether biospecimens can and should be 'repatriated.'

Human genetic research is a rapidly developing field that addresses a range of scientific and health problems. Our understanding of past human population movements and microevolutionary processes has greatly improved in recent years with advances in genomics and bioinformatics. In the field of health, the future of genomics promises a 'personalized' approach to medicine where many health care decisions are based on one's individual genome, a future foreshadowed by the direct-to-consumer genetic testing industry (*see* Direct-to-Consumer Personal Genetic Testing).

Indigenous people have been involved in many genetic ancestry- and health-related projects. (The Australian convention to capitalize 'Indigenous' is followed in this article.) Their participation has been sought out on the basis that their genetic material is highly informative for studies of population history and disease, but also because they may benefit, particularly from genetic studies of rare heritable diseases that affect their communities. However, Indigenous involvement in genetic research has often resulted in acrimony. These experiences reinforce the need for a robust and broad approach to ethics in this specialized research context.

It has been proposed that genetic and genomic research could help address health inequalities (Ramos and Rotimi, 2009). This includes Indigenous health inequalities, with reduced life expectancy at birth relative to the general population in the order of 5–10 years (Australian Institute of Health and Welfare & Australian Bureau of Statistics, 2008; Cooke et al., 2007). At the same time, Indigenous peoples have been identified as particularly at risk of 'group harms' from genetic research (Foster and Sharp, 2000; McGregor, 2010; Scott et al., 2005). Indigenous peoples have expressed concern that they do not sufficiently benefit from genetic research, that genetics diverts attention and resources away from nongenetic causes of health disparities including racism, and that genetic research could actually reinforce racism by implying that Indigenous people have genetic susceptibilities to disease and are thus inherently unhealthy (Dodson and Williamson, 1999; Paradies et al., 2007; Pearce et al., 2004). Others have criticized the lack of involvement of Indigenous communities in the planning of projects and insensitivity to cultural beliefs in the practice of the research (Arbour and Cook, 2006; Harding et al., 2012; Wallace, 1998; Chang and Lowenthal, 2001).

This article reviews the ethical issues that Indigenous people and others have raised with reference to genetic research projects and biobanks. It focuses on Indigenous populations within nation-states founded through British colonialism, primarily Aboriginal and Torres Strait Islander populations in Australia; First Nations, Inuit and Metis populations in Canada; Native Americans, Native Hawaiians and Alaskan Natives in the United States; and Maori in Aoteoroa/New Zealand. While Indigenous communities differ dramatically both between and within these countries, their common experience of British settler-colonization and the resulting nation-states provides a useful comparative base from which to examine their responses to genetic research (Cunningham and Stanley, 2003). Before discussing the relevant ethical issues, a consideration of the definition and scope of 'indigeneity' is required.

Who Is Indigenous?

The question of who is Indigenous is complex and often contested. The United Nations, for example, resists defining indigeneity, and the United Nations *Declaration of the Rights of Indigenous Peoples* does not offer any definition (United Nations, 2008). However, a publication of the United Nations Permanent Forum on Indigenous Issues indicates that Indigenous people have the following characteristics:

> "Self-identification as Indigenous peoples at the individual level and accepted by the community as their member; historical continuity with precolonial and/or presettler societies; strong link to territories and surrounding natural resources; distinct social, economic or political systems; distinct language, culture and beliefs; form nondominant groups of society; resolve to maintain and reproduce their ancestral environments and systems as distinctive peoples and communities." (United Nations Permanent Forum on Indigenous Issues, undated)

Three major themes are clear in this account: descent from precolonial populations; self-identification and community acceptance; and maintenance of distinct beliefs and practices. Indigenous people from the United States, Canada, Australia, and New Zealand have been the driving forces behind the international Indigenous rights movement and Indigenous scholarship

 http://dx.doi.org/10.1016/B978-0-08-097086-8.82058-9

(Niezen, 2003). Given that the literature on Indigenous genetic research has overwhelmingly focused on these countries, the author will follow suit here. However, Indigenous minorities numbering 370 million people have been recognized across 90 countries, and the issues discussed here may differ in each national setting and language group. Some of these issues have been explored in the literature in other contexts, such as Africa, but often through the concept of 'ethnic minorities' rather than Indigenous people (de Vries et al., 2012).

The Diversity of Indigenous People

Indigenous people are highly diverse at multiple levels: within individual Indigenous communities, between different Indigenous communities, and between different nations. To take Australia as an example, 74% of Aboriginal and Torres Strait Islander people live in urban and regional areas, and 26% live in remote areas. Only 12% of Aboriginal and Torres Strait Islander people speak an Indigenous language at home, with the remainder speaking English at home (Australian Bureau of Statistics, 2010). Over half of Aboriginal and Torres Strait Islanders overall have non-Indigenous partners, a figure that rises above 80% in urban areas (Khoo et al., 2009). These patterns, which are similar in North America and New Zealand, contribute to a highly diverse Indigenous population in terms of appearance, knowledge of traditional cultural practices and socioeconomic position. This diversity should be kept in mind throughout this article as the author's use of the term 'Indigenous people' may erroneously imply a degree of homogeneity.

Ethical Issues and Indigenous People

The ethical issues that apply to Indigenous people should be seen as additional to 'conventional' ethical issues that apply to all people, rather than replacing them. The standard ethical principles of autonomy, beneficence, nonmaleficence and justice, and procedures such as informed consent and ethical review, must be provided to Indigenous participants in genetic research. The additional ethical concerns that are reported in the literature are discussed in sections on group harm; cultural beliefs relating to biospecimens and human origins; community engagement and collective consent; benefit; ownership; and whether biospecimens can and should be 'repatriated.' This range of concerns derives from three interrelated sources: the distinctive cultural beliefs of Indigenous peoples (e.g., concerning blood samples); the collective nature of Indigenous societies (e.g., the need for collective consent); and the dispossession and marginalization of Indigenous people by the state.

In particular, experiences of dispossession, marginalization, and oppression have led many Indigenous people to distrust science and the dominant society in general. This lack of trust underlies many of the issues discussed below. The history of racial classification and stratification of Indigenous people by science and the state has enhanced the extent of suspicion of genetics as compared to other fields of science. In Australia, for example, the assimilation era (1930s–60s) is remembered as a time when the state sought to 'breed out the color' and make Aboriginal and Torres Strait Islander people 'white' through the removal of children of mixed heritage from their families. Many Indigenous people also associate contemporary genetic research with the long history of the procurement, circulation, and research of Indigenous human remains without consent (Bowekaty and Davis, 2003).

More recently, genetic research in Indigenous communities has spurred a number of controversies. The Human Genome Diversity Project (HGDP) is paradigmatic. This effort to collect DNA samples from Indigenous populations worldwide was dubbed the 'Vampire Project' by some Indigenous people and prompted the formation of the US-based international organization the Indigenous People's Council on Biocolonialism (*Indigenous Peoples Council on Biocolonialism*). The Genographic project, launched in 2005, is seen by some as repeat of the HGDP (Tallbear, 2007), although it has avoided the level of public criticism directed against the earlier project. Other recent controversies involving genetic research concern the Havasupai and the Yanomami (see **Box 1 and 2**). Some Indigenous groups have sought to avoid or ban genetic

Box 1 Havasupai

The Havasupai are a Native American tribe who live in the base of the Grand Canyon in Arizona. In the early 1990s they initiated genetic research into diabetes, as they were concerned about the rate of amputations caused by diabetes in their communities. Researchers obtained broad written informed consent for 'medical/behavioral research' when blood samples were collected. Samples were later used for a number of other studies without specific consent, including research into ancient population migrations into the Americas from Asia. The Havasupai discovered their samples had been used in this way when tribe member Carletta Tilousi attended a seminar at Arizona State University (ASU) in 2003. Tribal members felt that this research contradicted their cosmological beliefs and threatened their sovereignty. The samples were used for other studies into schizophrenia that had the potential to stigmatize the Havasupai. The tribe initiated legal action against ASU that was resolved in a settlement in 2010. As part of the settlement, 151 remaining samples were returned to the Havasupai in a ceremony conducted by tribal elders in the ASU laboratory. (Harmon, 2010)

Box 2 Yanomami

Anthropologist Napoleon Chagnon and geneticist James Neel collected blood samples from the Yanomami in Brazil and Venezuela in the 1960s and 70s. The samples have been held since that time at various laboratories in the United States.

In the last decade, Chagnon and Neel have been accused of unethical research practices in their dealings with the Yanomami, although these accusations have not been proven. In the midst of the controversy, the Yanomami began a campaign for the return of their samples on cultural grounds. When a Yanomami Indian dies, their body is cremated and no physical remains or possessions of the dead are kept. In this way, the Yanomami ensure that the deceased departs the world and separate the world of the living from the world of the dead. A blood sample held in a freezer may prevent this process from occurring. The Yanomami requested that samples be returned to them to be ritually destroyed by shamans and elders. Unlike the Havasupai case, the researchers and institutions involved with the Yanomami samples have never fought the tribe's requests. However, the task of returning the samples presents significant challenges. At the time of writing, the quest to return the samples had not yet overcome diplomatic and bureaucratic hurdles. (Couzin-Frankel, 2010)

research in their communities (Kowal et al., 2012; Navajo Nation Council, 2002).

It should be noted that Indigenous critiques of genetic research are one aspect of a broader critique of western research (Smith, 2012). Since the 1980s, Indigenous scholars have demanded that Indigenous people are active participants in research concerning their communities, or ideally, conduct their own research. These critiques have led to specific national guidelines for conducting research in Indigenous communities in Australia, Canada, and New Zealand (CIHR, 2007; HRCNZ, 2008; NHMRC, 2003). Recent reviews of guidelines have argued that the Canadian national guidelines provide the most comprehensive guidance for the conduct of genetic research (Jacobs et al., 2010; Taniguchi et al., 2012).

Group Harms

Many of the ethical issues specific to Indigenous people can be understood through the concept of group harm. Group harms are risks to a group that can arise from the process or outcomes of research. They can impact on the group as a whole or on individuals by virtue of their group membership (Hausman, 2008). The process of conducting a genetic research project can cause disruption in a community. For example, a study that found lower than expected Native American ancestry among participants had the potential to create conflict between different segments of the tribe who questioned whether study participants had the minimum required blood quantum for tribal membership (Foster and Sharp, 2000).

A wider range of group harms is associated with the outcomes of research. Many of these result from the way that Indigenous people are portrayed and treated in mainstream society. A research finding that a group is susceptible to a particular disease has the potential to increase discrimination against Indigenous people in a range of settings including interpersonal racism, racism in health care settings, or discrimination by insurers.

The concept of outcome-related group harm is illustrated by a research project on genes related to the enzyme monoamine oxidase-A (MAO-A) in a Maori population. The study aimed to understand genetic determinants of tobacco use and response to cessation treatment, processes which involve the MAO-A enzyme. However, the particular variant of the gene in question has also been associated with risk-taking and aggression, and is consequently known as the 'warrior gene.' The study was widely reported in the international media as proof that Maori were genetically predetermined to be violent. A Maori academic argued that linking the gene variant with high levels of violence among Maori is scientifically unsound, contributes to racial stereotyping, and may lead to genetic and racial discrimination by insurance companies (Hook, 2009: p. 6).

This example illustrates that while the risk of group harm is greater when the condition studied is potentially stigmatizing (e.g., a study of the genetic associations of alcoholism), stigmatization may be associated with the gene studied rather than the condition itself. All people who identify as Maori were at risk of potential harm from the outcomes of this project, whether or not they personally participated in the study. As Rothstein has noted, measures to protect individuals in research, such as the deidentification of data, do not address outcome-related group harms (Rothstein, 2010). Outcome-related group harms are by nature difficult to control. This highlights the importance of robust consent processes as discussed in the 'community engagement and collective consent' section below.

Cultural Beliefs

Some Indigenous groups hold cultural beliefs that have implications for the handling of biospecimens in genetic research. Indigenous scholars in Australia, the United States, and New Zealand have expressed that 'DNA is sacred.' This generally refers to the extension of holistic approaches to the body, the self, culture and nature to encompass DNA. Any part of the body, including blood or DNA samples, may be considered a piece of collective cultural heritage, indivisible from the self, other members of the group and the environment. This view is illustrated by the words of Native American geneticist the late Frank Dukepoo: "To us, any part of ourselves is sacred. Scientists say it is just DNA. For an Indian, it is not just DNA, it is part of a person, it is sacred, with deep religious significance. It is part of the essence of a person" (Dukepoo, 1998).

Indigenous people across the Pacific have argued that the use of blood and tissue samples can negatively impact on traditional spiritual beliefs. Blood samples are imbued with the 'life force' of the individual, known as *mana* in Hawaii (Fong et al., 2006), *ngeia* in Tonga (Dickenson, 2005) and *tapu* in Maori culture (Mead, 1996). The use of samples for purposes that are not explicitly consented, particularly in the case where the donor has died, can undermine the dignity of that person. For Maori, this can also have implications for donor's descendants. As Mead explains, "A physical gene is imbued with a life spirit handed down from the ancestors, contributed to by each successive generation, and passed on to future generations" (Mead, 1996). The misuse of blood samples is a violation of *tapu*, diminishing the amount of *tapu* available to descendants and affronting one's ancestors.

Indigenous people have drawn upon their cultural beliefs in devising culturally grounded approaches to genetic research and biobanks. Some Maori genetic research projects have involved the formation of a 'kaitiaki' group composed of Maori people who oversee the use of biospecimens and ensure that research protects Indigenous culture and benefits the community (Durie, 2004; Hudson et al., 2007). Durie describes a project where two elders were employed as 'spiritual guardians' for blood and urine samples, accompanying them to the research laboratory, inspecting protocols for biospecimen handling and disposal, conducting a ceremony to make the environment culturally 'safe' for biospecimen handling, and even traveling with the samples to a laboratory overseas (Durie, 2004). The Christchurch Tissue Bank in New Zealand is another example of the recognition of Indigenous cultural beliefs. It offers participants the option of having their sample disposed of with a Maori blessing or *karakia* when it is no longer required for research (Morrin et al., 2005). Such measures can be understood as attempts to reduce cultural harm (Tsosie, 2007).

Indigenous cultural beliefs about human origins are another potential source of contestation between scientists and Indigenous people. The cosmological beliefs of many Indigenous

cultures involve the idea that the group was created *in situ*, and did not migrate to their traditional lands from elsewhere. The dominant scientific account is that *Homo sapiens* evolved in Africa and migration from there to the rest of the world beginning around 100 000 years ago. Conflict between these two accounts has been most pronounced in North America, where Native Americans have taken offense at scientific explanations of Native American migration through the Bering Strait 15 000–45 000 years ago (Foster and Sharp, 2000). This issue is often at the center of contestation over scientific research on Native American ancestral remains (Tallbear, 2003), and the HGDP was also criticized on these grounds. Some have argued that scientific accounts of population history threaten Indigenous people's land claims and sovereignty rights (Harmon, 2010), although to date scientific knowledge about ancient population movements has not been used by any government to erode these rights where they exist.

Community Engagement and Collective Consent

Collective consent with Indigenous organizations is an important strategy to manage the potential risks of group harm and cultural harm associated with genetic research. As the risks cannot be entirely alleviated or prevented, it is important that (1) members of the collective are engaged at all stages of the project in order to influence the research questions, data and biospecimen collection, analysis and communication of results to minimize potential risks (and maximize potential benefits, see below), and (2) collective consent to conduct the research is provided in addition to individual consent from participants. An organization with a representative function in the Indigenous community of interest will consider the potential risks and benefits of the project *to the collective* and make a decision about participation. In many cases, permission or consent from an Indigenous organization is required to obtain a research permit or ethical approval.

Organizations such as tribal organizations (North America), iwi (tribal) health boards or organizations (Aotearoa/New Zealand) and Aboriginal community-controlled health organizations or land councils (Australia) regularly receive and process requests from researchers to conduct research in the communities within their purview. Information provided to collective organizations to inform the decision-making process would include the scientific rationale, potential risks and benefits of the study, confidentiality and privacy, return of results and genetic counseling (if applicable), ownership of samples and data, storage and disposal of specimens and data, third party use of specimens and data, future contact for additional research, withdrawal from research, intellectual property arrangements, commercialization, benefit sharing, and community review of draft publications. In some cases, researchers and Indigenous representatives will develop a formal Memorandum of Understanding covering some or all of these issues.

Community engagement can also inform the individual consent process, as indicated by a recent study of the attitudes of Alaskan Natives toward biospecimen handling and genetic research (Hiratsuka et al., 2012). Many participants believed that consent processes should disclose more information than is usually provided. They wanted to know, for example, "what type of container specimens are stored in, how exactly specimens are preserved over time (e.g., how they are protected from freezer burn), and the security of the storage facility … individuals mentioned a "destroy by" date or the option for choosing to have the sample destroyed after a participant's death" (Hiratsuka et al., 2012: p. 3). Community engagement and collective consent can reveal local preferences for biospecimen handling and what should be discussed in the consent process.

Genetic research often involves storing samples for unknown future uses, either within an established biobank or an individual project collection. In such cases, researchers often obtain 'broad consent' for future uses. However, within Indigenous research there is a general movement against broad consent, which may be considered insufficient to protect against group harms. For example, the Indian Health Service guidelines for handling biospecimens note that broad or 'blanket' consent is by definition uninformed, as it allows for potentially stigmatizing research to occur, such as research into the genetics of alcoholism (Freeman, 2001). Instead, consent should be specific to a project or a limited range of future research.

While these approaches to limiting group harm address some important problems, they raise others. Both collective consent and specific consent invoke the possibility that the individual autonomy of an Indigenous person to consent to research, or to provide broad consent, could be overridden by the decision of a collective body. In some instances, such as biobanks, an injunction against broad consent could exclude Indigenous people from participating if other models of consent are not available (e.g., because there is insufficient funding to request individual consent for each future use). These problems are partially addressed through incorporate Indigenous governance into a biobank, as discussed in the conclusion.

Benefit

Research participation is thought to significantly depend on altruism, with research participants contributing toward scientific discovery in order to benefit society as a whole. Genetic research is likely to involve long lead times before any benefits accrue, such as improvements in health care. Indigenous people may not perceive that they benefit from general medical and scientific advances because of their marginalization from mainstream society and poor access to health care (Du Plessis et al., 2004). Bad experiences of genetic research, such as those examples discussed above, can reinforce the perception that Indigenous people will not benefit.

For these reasons, ethical guidelines indicate that research should offer direct benefits to Indigenous communities (CIHR, 2007; HRCNZ, 2008; NHMRC, 2003). For example, providing employment, training, and professional development opportunities for Indigenous people ensures that Indigenous communities directly benefit from research projects and build the capacity of the Indigenous research workforce.

Ownership

The cases of John Moore and Henrietta Lacks attest that donor property rights over samples and data has long been a vexed

issue in human biospecimen research. Current ethical approaches tend to focus on autonomy and sidestep issues of ownership (Charo, 2006). In an Indigenous context, cultural beliefs about biospecimens outlined above can encompass collective ownership of samples. Indigenous communities often view their natural and cultural resources as collectively owned. In cases this has been explicitly extended to DNA, whereby the DNA of an Indigenous person is the property of the collective as well as the individual (Mead, 1996; Dodson and Williamson, 1999). This is more likely to apply when researchers collect biospecimens in order to 'represent' the genetic variation of the collective (Indigenous Peoples Council on Biocolonialism, 2000).

The principle of collective ownership forms the basis of Arbour and Cook's concept of 'DNA on loan.' They argue that, "in keeping with cultural perspectives and the principles of participatory action research," biosamples should be considered the property of individual donors and the community. Samples are 'on loan' to researchers who act as 'stewards' (Arbour and Cook, 2006). Arbour and Cook do not discuss the legal implications of recognizing the body as property. In practice, the legal limitations of the concept may be of little consequence: the principle of 'DNA on loan' works to ensure that the individual and collective autonomy of Indigenous donors is respected. It addresses a core concern that Indigenous people from various countries have expressed about genetic research: the use of biospecimens (and data) for research that they do not agree with on cultural or moral grounds (Cunningham, 1998; Du Plessis et al., 2004; Foster and Sharp, 2000; Indigenous Peoples Council on Biocolonialism, 2000). It is not surprising, then, that a key consequence of retained donor ownership of samples is that specific consent (from individuals or community organizations) is required for any use of samples or data beyond the initial project, even if samples or data are used without identifiers (Arbour and Cook, 2006). This relates to the move away from broad consent discussed above.

'Repatriation' of Blood Samples

The concept of a loan implies an eventual return. Arbour and Cook do not discuss this issue, although the Canadian Institutes of Health Research guidelines (which draw on the concept of samples 'on loan') state that researchers should outline whether samples will be returned "if possible, and desired by the research participant" (CIHR, 2007: p. 32). This raises the question: is the return of blood samples to Indigenous people an instance of 'repatriation'?

The repatriation of ancestral human remains held by museums and universities to the Indigenous community of origin began in the 1980s in response to international campaigns by Indigenous activists. It has become a widespread practice in Australia, Canada, the United States, New Zealand, and more recently Africa. It is guided by national legislation such as the Native American Graves Protection and Repatriation Act 1990 (NAGPRA) in the United States as well as various institutional policies.

Under most definitions, human remains are bodies or parts of bodies originally intended for burial. Blood or saliva samples collected for scientific research are therefore not recognized as human remains for the purposes of repatriation. However, the term 'repatriation' is used by commentators discussing the return of blood samples to the Havasupai and Yanomami, and the 2004 case of the Nuu-chah-nulth in Canada (Reardon and TallBear, 2012; Wiwchar, 2004). This remains an emerging ethical issue in Indigenous genetic research that could affect many thousands of old biospecimens currently held in institutions around the world.

An important implication of the 'repatriation' paradigm is that it acts across national borders. While the various ethical issues the author has outlined in this article are enshrined in national guidelines and are built into ethical review, the use of previously collected Indigenous biospecimens in countries other than where they are collected occurs outside such guidelines. This issue was highlighted in 2011 when the 'first Aboriginal genome' was sequenced by a team of researchers based in Denmark using a hair sample collected in 1932 from a train station in remote Western Australia and held at the University of Cambridge. Researchers sought approval for the study from an Aboriginal land council in the region where the sample was collected, even though the Danish ethics committee that approved the study thought this unnecessary (Calloway, 2011). It is likely that the distinction between human remains destined for repatriation and biospecimens available for scientific study will continue to be a source of ethical uncertainty.

Conclusion

Scholars have expressed optimism about 'bridging the divide' between genomics and Indigenous peoples in order that Indigenous people can benefit from the potential of genomics to improve their health (Jacobs et al., 2010). Clearly, there is much work to be done to address the ethical concerns that Indigenous people have raised, particularly unresolved and emerging issues such as collective ownership of samples, repatriation, and the use of Indigenous biospecimens that exist beyond national borders.

The creation of biospecimen collections under robust Indigenous governance is one way to address many ethical concerns. A prominent example is the Alaskan Area Specimen Bank, a resource of over 500 000 biospecimens of which 76% were collected from Native Alaskans. The collection is governed by the Alaska Area Specimen Bank Working Group, a body that includes representatives from Alaskan Native Tribal Health Organizations and the Indian Health Service. All projects that seek to access the Bank need approval from a Tribal Health Organization, and also require individual consent if identifying information is to be used (Parkinson et al., 2013). Another newly established collection of Indigenous biospecimens under Indigenous governance is the National Centre for Indigenous Genomics at the Australian National University.

Tools to educate and empower Indigenous people to take an active role in genetic research projects are another mechanism of 'bridging the divide.' Again, the United States offers the most advanced models. The *American Indian and Alaskan Native Genetics Resource Center* is a Web site developed by the National

Congress of American Indians to provide resources for tribes who are considering participating in genetic research or developing their own research projects (*American Indian and Alaska Native Genetics Resource Center*). Another key initiative is the Summer Institute for Native Americans in Genomics, hosted annually at the University of Illinois since 2011 and open to Indigenous people from across the Americas (The Institute for Genomic Biology). It aims to introduce participants to the principles and practices of genomics and informatics; facilitate discussion of bioethics in Indigenous genetic research; and promote science careers for Indigenous people. Similar initiatives in other countries would promote ethical practices in Indigenous genetic research.

Understanding the ethical issues related to Indigenous genetic research is important to uphold the rights of Indigenous people, and also has wider relevance. Bioethicists are increasingly looking to Indigenous research ethics to inform wider practices (Mello and Wolf, 2010; Rothstein, 2010). As Taniguchi et al. have recently phrased it, "Indigenous groups are most vulnerable to research exploitation and harm; therefore, identifying principles that work for Indigenous people will lead to best practices for all populations" (Taniguchi et al., 2012). The ethical innovations and uncertainties of Indigenous genetic research are important considerations for everyone concerned with the genomic future.

Genetics and Social Justice

Lindsay A Smith, University of New Mexico, Albuquerque, NM, USA

Abstract

This article examines four genetic technologies as they have been articulated as tools for social justice: kinship analysis in postconflict settings, forensic DNA and criminal exoneration, genetic testing and women's health, and golden rice and food security. The cases highlight the potentials and pitfalls of science in the service of justice and the importance of recognizing technologies as hybrid political and scientific tools best implemented within a politics of humility and governed by social actors rather than scientists.

From the earliest days of genetics, concerns for social justice have been embedded it its practice. Since the days of Galton's coining of the term eugenics in the years after reading his cousin Darwin's monograph *On the Origin of Species*, there has been an enduring preoccupation with the potential for genetic knowledge and technology to both explain and shift the inequalities of human society (Gillham, 2001). In the twentieth century, new technologies like karyotyping and recombinant DNA were directly applied to social concerns through medical and agricultural technologies like prenatal genetic testing and genetically modified crops. As the controversies surrounding these examples show, however, scientific solutions to complex social problems like human reproduction, disability, and the global population boom, have also generated intense ethical debate and, in many cases, contributed to real and lasting social harm. Given this complexity, can genetics be used as a tool for social justice?

Genetic technologies and social justice movements have coalesced around four major areas: (1) the family and kinship; (2) criminal justice and forensics, (3) human health and disease; and (4) environment and sustainability. Highlighting one technology in each of these categories, this article offers a review of the challenges of genetic technology-driven social justice movements. Rather than focus only on successful sites of intervention, these cases emphasize the need for deliberation and suggest three common challenges of genetics as a tool for social justice: the use of race as a proxy for genetic difference, biological reductionism, and commercialization. The review suggests that genetics best coalesces with the goals for social justice in cases where technology is governed by a politics of humility, owned and managed by social rather than scientific actors, and conceived of as one tool within broader social and political movements rather than a magic bullet capable of quickly cutting through messy social issues.

Genetics and Social Justice: Between the Individual and Society

The sequencing of the human genome in 2000 heralded the unlocking of the secrets of humankind. As a scientific benchmark, the human genome project promised revolutions in the management of disease, health, morphology, development, and evolution. The sequencing of the genome also offered an important platform for social justice by establishing humanity's 99.9% genetic similarity. Revealed were humans' deep interconnections, literally through ties of marriage and reproduction and metaphysically through millions of years of evolutionary development. At the same time, the genetic revolution also inaugurated a focus on the individual specificity of every human being and much of the technological innovation of genetics has focused on individuation.

Justice, like genetics, also straddles this uneasy divide between the collective and the individual. In contemporary usage, social justice can be synonymous with human rights, refering to reform or change at a collective level to ameliorate the deep and lasting disparities between particular segments of society. Social justice, as a theoretical concept, emerged as a critique of traditional theories of justice, which had focused on individual good and interpersonal harm through the rubric of property. With the rise of labor and social reforms in the face of the expanding inequalities of the Industrial Revolution, thinkers and activists sought to articulate new formulations of justice to account for the harm done by structural inequalities and the reproduction of social class. Where traditional forms of justice have focused on individual violations codified under penal and civil codes, social justice has worked at the level of the harms caused by the status quo of social and state structures (Capeheart and Milovanovic, 2007).

Justice and genetics meet in this uneasy space between the individual and the collective. For genetics, this has been articulated in debates about whether the potential of the field is best realized through greater personalization and individualization or through an emphasis on similarities and shared evolutionary history. Social analysts of genetic science have pointed to the importance of a balanced focus on the dynamic interplay of these population and individual forces rather than a single causal explanatory framework (Lewontin, 2001). These questions are subjects of important debate in society and highlight the paradoxical nature of both genomic science and social justice at the intersection of the individual and society. When genetic technologies are developed as a potential intervention into inequality, they necessarily invoke a third social sphere of institutional policy and power. In cases where science works toward social justice goals, the hybrid reality of all science and technology becomes apparent as innovations within laboratory walls are invested with social, legal, or state power.

Historical Background: Eugenics and the Progressive Spirit

Eugenics remains a necessary starting point for considering the tight linking of societal and genetic technologies. Although eugenics is now roundly rejected as ideologically driven pseudoscience, in its heyday this scientifically driven social reform was championed as a powerful way of enacting social justice. Many liberal reformers of the day saw eugenics as a humane and effective way to stamp out systemic social ills like poverty, alcoholism, and mental illness. Encouraging "better breeding" through selective marriages between individuals with socially valued, culturally determined traits from ethnic phenotypes to perceived intelligence and economic productivity and discouraging the reproduction of "feeble" stocks. Advocates of eugenics as social improvement argued that this science would, within a few generations, transform human populations, much like agricultural breeders had created new productivity and utility out of the germplasm of domesticated animals and plants. Oliver Wendell Holmes, the Chief Justice of the Supreme Court and renowned American progressive, even wrote the majority opinion upholding the right of the state of Virginia to sterilize Carrie Buck an institutionalized young woman whose mother had also been found social unfit. He summed up the eugenic ethos of selective breeding as public good in his 1927 majority opinion. Comparing tubal ligation and vaccination as legally equivalent public health measures, he declared that this preventative act would do much more for the social good than subsequent more punitive, responses to the social results of bad breeding: "It is better for all the world if, instead of waiting to execute degenerate offspring for crime or to let them starve for their imbecility, society can prevent those who are manifestly unfit from continuing their kind" (*Buck v. Bell*, 1927).

Genetic technologies in the form of early eugenics were complicit with some of the worst human atrocities of the twentieth century. This period of genetic research is notable for its employment of genealogical studies of traits and the early development of twin studies, which remain standard techniques of genetic research. However, eugenics ended in brutal practices of forced sterilization in Europe and the United States and ultimately genocide during the Second World War (WWII). It is important to consider eugenics within a broader analysis of genetics and social justice, because it highlights the ways in which justice and social good are not absolute qualities, but rather have been and continue to be the subject of fierce ideological and political battles. Scientific technologies are part of ideological systems of social transformation, coming into being not as value-neutral tools for truth but because of politics, moral beliefs, and visions for particular kinds of futures.

Given this violent history, human genetics in the 1950s reformulated itself through the Modern Evolutionary Synthesis toward a focus on development, fitness, and discrete measurable traits. As human and medical genetics reached a new level of utility with the ability to visualize chromosomes through karyotyping (e.g., tests for autosomal anomalies, chromosomal based sex determination) and later manipulate and sequence the genome, it also increasingly had direct applications in human life and biology. This emerged in legal contexts as paternity testing and later DNA analysis and kinship analysis, in medical contexts as organ donor matching, amniocentesis, genetic registries for recessive diseases, and most recently preimplantation genetic diagnosis, and in agriculture through increased experimentation and control over plant and animal breeding. With this rapid expansion of genetic technologies, new debates arose over their potential for both social good and the hardening of biological notions of human difference.

Family: Kinship Analysis and Transitional Justice

Nelida Navajas received a phone call right before bed on the 13 July 1976. The woman on the line told Nelida to come quickly to her daughter Cristina's apartment because the children were alone and crying. When she arrived at the apartment, she could hear the children screaming from the sidewalk as she parked her car. She ran upstairs to find the apartment in disarray and three distraught children, her grandsons and their cousin. Nelida's pregnant daughter and the two other women, who had been caring for the children, had been forcibly detained by masked men with guns. Nelida never saw her daughter again. Cristina became one of the 30 000 *desaparecidos*, disappeared men and women, who between 1976 and 1984 were forcibly detained by the Argentine military dictatorship as part of a violent military crackdown on social and political life under the guise of a 'dirty war' against communist subversives (CONADEP, 2003). For years, Nelida explained, she could not hear the sound of a child screaming without getting sick (Nelida Navajas. Interview by author. 2005.).

While her daughter and the child Cristina was pregnant with continuing to remain disappeared, Nelida spent her life searching for them. She was a founding member of the *Abuelas* (Grandmothers) of the Plaza de Mayo, an organization of women dedicated to finding their missing children and grandchildren. Through their activism the Abuelas discovered that the military dictatorship was trafficking in the children of young women like Cristina, rather than killing the babies when they were born. Nelida's grandchild and an estimated 500 other missing children were likely alive, appropriated by military families or others with close ties to the ruling class. The Abuelas had found evidence of the survival of their missing grandchildren, but did not know how to prove their relatedness to these children so that they could be legally returned to the families in which these babies were born. In 1976, when Nelida's grandchild would have been born and illegally trafficked by the government, genetic testing for relatedness was in its technological infancy. Developments in organ transplant technology and histocompatibility studies among families, led the scientists the Grandmothers consulted to believe it might be possible that, based on blood alone, genetics could establish the relatedness between a grandchild and grandparent in the absence of the parental generation. A transnational team of scientists under the aegis of the American Association for the Advancement of Science (AAAS) developed the first genetic tool for human rights, the Index of Grandpaternity, which in 1984 was used to return Paula Logares, who was born in captivity, to her grandmother (Arditti, 1999). This use of genetics to connect families separated by genocide, though routine in the present, was technologically impressive and politically unprecedented in 1984. Scientists, like Mary Claire King, who headed the AAAS

team as well as other members, developed a new agenda for politically engaged scientists to use their expertise as tools for social justice. From the tsunami in Thailand to the World Trade Center in the United States, family groups, scientists, and activists have worked together to create DNA databases for the purposes of family reunification. This work has focused both on identifying the dead as in Bosnia after the genocide at Srebrenicia, and the living, as in the case of children displaced or kidnapped during the chaos of war and disaster.

Criminal Justice: Forensic DNA and Wrongful Convictions

After serving 11 years of a 27-year criminal sentence, Mr Anthony Robinson was released on parole. Convicted in 1987 of raping a white college-aged girl in the University of Houston campus, Mr Robinson had maintained his innocence throughout his trial and prison term. When he was released on probation, he worked until he had made enough money to hire a lawyer. Even his lawyer did not believe his story and suggested he save the funds to have the biological samples from his case undergo forensic DNA analysis. They would wait and see what the results showed before pursuing the case aggressively. At the time of his trial, forensic DNA typing was not widely in use and blood typing was the primary forensic evidence presented. Although he petitioned up to the Supreme Court to have his case reexamined, his conviction stood. Robinson, now a lawyer, understood his case as emblematic of a racist judicial system. As a black man in the South, accused of raping a white woman, old prejudices ran deep, coloring the interpretations of everyone involved from the jury and judge to his own public defender. They could not see beyond their prejudices and believe his claims of innocence. Like many of the other 316 individuals who have been exonerated through the work of the Innocence Project, a group devoted to using forensic DNA to address wrongful convictions, Mr. Robinson found himself caught up in the structural inequalities of American justice. Although his words were disregarded, the forensic DNA test corroborated his claims of innocence, showing that the body fluids at the scene of the crime did not match him. In 2000, after the test was repeated by the Texas authorities, Anthony Robinson was officially pardoned (Anthony Robison. Interview by author. March 2002.).

The Innocence Project was founded in 1992 through collaboration between Barry Scheck and Peter Neufield at the Cordozo Law School. It is dedicated to helping prisoners gain accesss to resources to contest wrongful convictions. Although the organization now works on cases where DNA identification is not applicable, its initial mission was to bring the power of genetics to victims of an unjust system. DNA, in the eyes of the founders, both veterans of the OJ Simpson defense team, had the potential to offer a new kind of objectivity in some of the most problematic crimes: murder and sexual assault. As defense lawyers, they understood the system as inherently biased against the poor and people of color, leaving an overwhelmingly disproportionate number of black men behind bars. Forensic DNA analysis, although controversial scientifically when it was first introduced as a tool of criminal prosecution (Aronson, 2007), nonetheless had exceptional strengths for exoneration in these cases. Including someone as a potential perpetrator, of a crime especially in the earliest days of genetic technologies, when the statistical power of matches was relatively low, was legally problematic; but excluding people was straightforward. If the biological sample from the crime scene and the sample from the person convicted for the crime did not match at the loci tested in the genetic analysis, the DNA test provided powerful proof of their potential innocence. The logic behind this appeal to genetics was that the objectivity of science could serve as a corrective to the structural inequalities of the justice system. Genetic technologies would be the agents of social justice where other legal systems of review, like the appellate system, had failed. As of 2014, the Innocence Project had helped to exonerate 316 individuals, including Anthony Robinson. Although genetic analysis is not applicable in most criminal cases, the organization sees genetic science as a means of providing visible proof of the failures of the justice system and thereby galvanizing change.

Health: Genetic Testing for Breast Cancer and Health Disparities

In 2013, the actress Angelina Jolie, published an op-ed in the *New York Times* describing her decision to undergo a double mastectomy and breast reconstruction because of her family history of cancer and her positive finding of a mutation in her BRCA1 gene. She describes the difficulty of losing her mother to breast cancer and explaining this loss to her children especially knowing herself to be a carrier of a "'faulty' gene, BRCA1" which greatly increases her risk of the breast and ovarian cancer (Jolie, 2013). In radical detail, Jolie lays out her experience of the procedure of double mastectomy: the preparation to save sensation in her nipples, the marathon surgery to remove her breast tissue, and the pain and mess of recovery. Jolie offers an intimate portrayal of a radical choice. As an actress, who has routinely been sexualized and idealized as one of *People Magazine's* most beautiful woman, her frank discussion of risk, surgery, and recovery had important effects on popular conceptualizations of breast cancer genetics, risk, and the violent choices of prophylaxis. Her op-ed concludes by alluding to underlying social justice potential of genetic testing for a disease that claims the lives of so many women. She encourages women to get tested. Mentioning the cost of testing as a barrier, she alludes to, although does not discuss, the contemporaneous issue of BRCA1 and BRCA2 patents and their effect on research, the cost of testing, and by extension the lives and mortality of women at risk for hereditary breast cancer. Using her influence as a Hollywood star, Angelina Jolie offers a portrait of genetic testing for breast cancer as giving women choices and control over a terrifying illness.

Angelina Jolie's very public discussion of this topic and her own choices in the face of new genetic knowledge, come at the end of more than a decade of research on the genetics of breast cancer. Mary Claire King, who also played a central role in the development of human rights genetics in Latin America, was a pioneer in this field, honing in on the potential loci for these tumor suppressor genes which were known to play an important role in the etiology of breast and ovarian cancer. In the film, *In the Family*, a documentary chronicling Joanna Rudnick's

experience with BRCA testing, King is interviewed and she describes the importance of this focus on the genetics of women's health as concrete form of empowering women with knowledge and choices about their body (Rudnik, 2008). Gendered health disparities are addressed in the same language as the feminist body politics surrounding pregnancy and abortion. Genetic knowledge is coded as empowering choice through basic genetic research and increasing women's access to testing. Although advances in BRCA testing are heralded as an important first step to addressing women's health, advocates acknowledge that much work remains to be done to give women better options than preventive mastectomy in the face of a positive test result through more robust education about risk, prevention, and treatment (Parthasarathy, 2012).

Biodiversity: Golden Rice and Food Security

Upon his retirement, Ingo Potrykus, a European geneticist, whose career focused on agricultural biotechnology, published a summary of one of his major life achievements, the development of 'golden rice' (Potrykus, 2001). His early interest in the potential of transgenic crops to alleviate food insecurity, found form in the successes his laboratory had in the genetic modification of rice. Although he began his career working in more esoteric crops like tobacco and petunias, his realization of the social justice potential of genetics in food security converged on rice because of its centrality as a sustenance crop in the developing world. In the article, Potrykus describes the scourge of Iron and Vitamin A deficiency and the drawbacks of rice as a staple crop given its deficiency in these nutrients. With the support of the Rockefeller Foundation, what he later understands as a fortuitous reliance on public rather than private support, Potrykus' laboratory inserted two genes into rice which formed a molecular pathway for the production of Betacarotene and gave the rice its golden hue. Potrykus offers golden rice as a potential corrective for the general mistrust and negativity surrounding genetically modified crops because, from its funding model to its distribution model, golden rice innovates to address illness and food security in a single improved crop.

Despite the seeming promise of the technology, golden rice has not yet been implemented on a wide scale in any developing context because it has met with entrenched local and global resistance. It has, however, been successful in offering alternative public narrative for genetically modified organisms (GMO's) beyond the critique of the multinational control of food production represented in genetically modified plant and pesticide systems, like 'Roundup Ready' Soy and BT cotton (Stone, 2010). Proponents highlight the crop as a model because of its development through publicly funded research, innovative patent licensing that could make the rice available to the poor, and the potential of this fix to address preventable childhood blindness due to vitamin A deficiency. India has been the primary target of this intervention, and advocates point to the potential important cultural resonances that a yellow rice might have given the widespread use of saffron to achieve this same effect for ritual purposes. Rather than an economically driven attempt to control agricultural markets, golden rice is offered as a way to enhance local farming, health, and cultural life.

Opposition to Social Justice Genetic Technologies

Postconflict DNA identification, DNA-led exonerations, breast cancer genetic testing, and golden rice can be broadly understood as social justice genetic technologies, that is technologies whose development and application have been inextricably intertwined with claims of justice, equity, and societal amelioration. However, this framing tends to overemphasize the intentions of the scientists and advocates developing the technologies and ignore the inevitable friction between intentions and social realities. Each has also met with broad and sustained opposition. The controversies that have emerged when genetic technologies are taken up as pathways to social justice, point to the complexity of the very concept of justice. In addition, these technologies are embedded within a larger ideology of science which presents technology and knowledge as fundamentally apolitical and teleological with knowledge production marching unceasingly toward truth. Science and technology scholars, however, have shown that knowledge is political. From the macrostructures of funding and research agenda-setting to the micropolitics of laboratory life, science like all human endeavors is embedded in systems of power. Initiatives in genetics to address human inequality and social suffering do not escape these same power structures simply because of the good intentions of their creators. As the historical case of eugenics illuminates, broader social ideologies can be reinforced through technological development and practice.

Scientific social justice initiatives often have a familiar narrative structure to their development: socially committed scientists recognize that through their specialized skills they might be able to decrease inequality and address specific social harms. We see this in all the cases discussed, from eugenics to DNA-led exonerations and biofortified GMO crops. Scientists like Mary Claire King, who has focused her career on science in the public interest, offer an alternative to the increasing corporatization of the Academy, where technologies are funneled through technology transfer offices and patent regimes to biotechnology start-ups and industry. Socially committed science, rather than justifying its existence through an appeal to innovation or capital generation, instead offers the public good as its ultimate aim. Increasingly, this justification of public good has become normative as researchers are required to enumerate in funding applications the ways in which the knowledge they generate will reach and benefit the public.

The opposition to genetic technologies, even ones framed with explicit social justice goals, has fallen into three major arenas: the role of genetics in reinforcing biological notions of race and practices of racism, biological reductionism, and the corporate control of life. The sophisticated and insightful critiques of postconflict DNA identification, DNA-led exonerations, breast cancer genetic testing, and golden rice all point to the ways in which these technologies resonate with broader ideologies about genetics and human identity, meanings of family, life and ownership, and race and racism.

Race and genetics have a long and troubled history. The use of race as a biological category to explain patterns of human difference was a standard practice of nineteenth century science, within a broader political context of human exploitation and colonialism. With the sequencing of the human genome, ideas about race have been publicly eschewed in favor

of the concept of population. Despite the scientific consensus around the biological nonexistence of race, technologies have continued to rely on race as a proxy for ideas about group differences, which are further reinforced by the pervasive racial ideologies in American society, where much of the technology is developed. In criminal justice and medical settings, in particular, race becomes the default social category for genetic technologies. Statistical probabilities of genetic matches and the relative risk of disease are broken down by racial grouping. Developers and users of these technologies see race as a helpful proxy, while critics have clearly shown that this continued reinscription of race as a meaningful biological category in everyday interactions with genetics, reinforces ideas about inherent biological differences between social groupings (Roberts, 2012). An unintended consequence of genetic technologies aimed at social justice that embed race in their form and function can be the hardening of racist ideologies about groups already stigmatized and oppressed. This has been an important critique of initiatives around human identification like kinship analysis in postconflict settings and DNA-led exonerations. BRCA testing has also unintentionally reinforced racialized health disparities, with current tests remaining much more effective and available for white women than for women of color despite deep differentials in cancer-related deaths (Hall and Olopade, 2006).

Closely tied to the biological hardening of racial ideologies has been the critique of genetic technologies as reinforcing biological reductionism, the use of biology as the primary and fundamental explanatory framework for human behavior and social relations. This move toward biological explanation leaves out the role of social life and by extension power and inequality in human outcomes. Vandana Shiva's trenchant critique of golden rice illuminates how Vitamin A deficiency is not driven by rice or cultural practices of rice consumption but by poverty which forces entire segments of society to subsist on rice alone. Rather than modify rice, she argues, how might we modify society to foster farming and land tenure practices that restore traditional cultivars thereby addressing inequality-driven hunger. By reducing vitamin A deficiency to a biological problem, the answer becomes technological: improve rice. But when the broader social picture is restored, it becomes clear that the problems underlying nutrient deficiency are both biological and social and solutions must take both into account (Shiva, 2001). This same critique is important in cases of postconflict DNA identification when the widespread use of kinship analysis, which relies on biological notions of family and relatedness, interacts with diverse social practices of family formation. The technology, unintentionally through its form, reinforces narrow ideas of family based in heterosexual reproduction and biological relatedness. This leads to misunderstandings between scientists and victims in postconflict settings when individuals, which scientists understand as nonrelated, repeatedly attempt to donate DNA samples for identificatory purposes; it also points to the vibrant and varied human practices of love, obligation, and belonging that must be understood to successfully address the legacies of violent conflict.

One of the most visible and successful critiques of genetic technologies has been around the corporate control of life, specifically through patenting regimes. The environmental and antiglobalization movement have joined together in their resistance to intellectual property regimes. This critique understands the problem of biotechnology to be one of the ownership of knowledge and by extension the corporate control of the biodiversity of life. Golden rice has been a key player in these debates. Corporate sponsors highlight its potential as a public good emerging from a successful and benevolent intellectual property regime. Critics argue that a public good like rice should not fall into the realm of benevolent charity but instead remain part of a fundamental right to access the global commons of biodiversity. Genetic testing for BRCA genes has played a historic role in this fight, becoming in and of itself a rallying cry for social justice. The American Civil Liberties Union (ACLU) along with many partner organizations challenged the right to patent genes. The case focused on Myriad Genetics, which held the patent on the BRCA genes and was the sole purveyor of testing. In 2013, the United States Supreme Court ruled that human genes, in the form of a naturally occurring sequences, could not be patented, reversing years of biotechnology practices of patenting genes as soon as they were sequenced (*Association for Molecular Pathology v. Myriad*, 2013). This ruling was heralded as an important social justice accomplishment in the realm of genetics, one which enshrined the human genome as a public good.

The Governance of Genetic Technologies for Social Justice

The governance of technology focuses directly on the issue of power and politics within knowledge production. Who decides what technologies should be developed and how they should be implemented and regulated? Formally this often falls on the shoulders of governmental regulatory bodies but as in the case of the BRCA patents, courts of law also play central role as a space for the public and other interested parties to contest scientific technologies and practices and their impact on social life. In cases where urgent social justice ends are at stake, like the identification of missing children in Argentina, technologies are often developed and implemented under a logic of crisis, which can trump ethical deliberation. The controversies social justice genetic technologies have generated suggest that to be successful in their aims, geneticists must move beyond crisis thinking to deliberate with the public about how to best address social harms and avoid the pitfalls of racialization, biological reductionism, and privatization of genetic resources. Looking at the case studies together, an important theme in social justice genetics has been the public ownership and management of technologies. For example, the Abuelas of the Plaza de Mayo worked in collaboration with scientists to develop the Index of Grandpaternity to specifically address the brutal nature of disappearance in Argentina. Women directly affected by genocide decided the needs and parameters of genetic intervention and subsequently directed the use of the technology: who would be tested, in what ways, and to what ends. In contrast, the genetic technology of golden rice, although designed to address perceived problems of poverty, was not integrated with local communities' needs and approaches to hunger alleviation. Genetics, if it is to be a tool for social justice, must be practiced with a politics of humility (Jasanoff, 2007) that understands genetic technologies as

inherently political, as partial and socially embedded, and only effectively implemented and governed through a robust and equitable collaboration between science and society.

Genetics and Society

Abstract

Following the breakthrough of the development of recombinant DNA in the 1970s, scientific research in genetics has grown exponentially. Social science, and in particular sociology, has taken a little longer to catch up following closely on the heels of ethics and philosophy. Strands from medical anthropology and sociology, law, environmental issues, science policy studies, and the public understanding of science have together formed a bricolage of approaches that underpin a discussion of the relationship between genetics and society. It follows with a discussion of a selection of both empirical and conceptual advances in genomics and stem cell technology, before concluding by indicating some future directions in which social science is heading. Finally there is a short appendix with online links to several useful Web sites.

Introduction and Intellectual Antecedents

The relationship between genetics and society has proved to be a complex one since the link between Herbert Spencer's Social Darwinism and the rediscovery of 'classical' (transmission) genetics in the work of Gregor Mendel was made at the end of the nineteenth century. The early decades of the twentieth century saw the applications of genetic research as relatively uncontentious. Much of the focus was on raising living standards by improving livestock strains and developing food production through more efficient plant breeding (Bud, 1993). Societal concerns focused on the growing eugenics movement with its aim, made explicitly by Francis Galton who coined the term in 1883, to improve the social condition by using similar methods. Both can be seen as responses to the rapid and unimagined consequences of the process of industrialization and urbanization overtaking many western societies at that time. As Koch (2009, p. 438) points out, linking science and social policy to move from natural to artificial selection was seen as a progressive way to enhance the quality of the citizenry. She also makes it clear, however, that eugenics is by no means a unitary concept, and its meanings are historically and culturally grounded. Much of the same can now be said for the concept of the gene (Keller, 2000, p. 67). The rise of Nazi Germany, the War, and the Holocaust all contributed to muting many of the advocates of eugenics in many of its forms (Kevles, 1992). The immediate postwar period also saw the molecularization of the concept of the gene culminating in the discovery of the double helical structure of DNA in 1953 (Watson and Crick, 1953).

In the 1960s and 1970s, several groups of social commentators and concerned scientists began to publicize the potential dangers of a wide range of scientific and technological advances, including most notably nuclear and biological weapons (Maddox, 1972). The ideological debate about the status and role of science and technology in contemporary society gathered momentum with the advent of antinuclear groups such as the Campaign for Nuclear Disarmament, environmentalist movements led by Rachel Carson's *The Silent Spring* (1962), and anti-Vietnam war protestors (Krimsky, 1982; Rose and Rose, 1976). Together these social movements formed the backdrop to the discovery of a key moment in the relationship between genetics and society: genetic manipulation. Popular culture has a long history of describing the intended and often unintended consequences of directing nature according to the whims of individuals or social groups with noteworthy contributions by among others, Mary Shelley, HG Wells, and Aldous Huxley (Turney, 1998). Now for the first time it seemed fiction might be turned into fact with the first publication using the new technique of recombining DNA (in *Escherichia coli*) appearing in 1972 (Jackson et al., 1972). However, the wider public expressed great concern about the dangers of the new technique, and even the scientists were not immune to the reservations being expressed within society at large. In 1973 a group published a letter in *Science*, the journal of the American Association for the Advancement of Science, asking for the dangers surrounding the creation of new hybrid viruses with unpredictable biological properties to be formally investigated. Following almost a year of investigation a second letter calling for a moratorium on certain kinds of rDNA experiments was published marking one of the very few occasions in the history of science when scientists themselves have called for their research to be stopped until appropriate restraints have been put in place (Krimsky, 1982; Bennett et al., 1986). The practical outcome of these events was the establishment of rigorous guidelines around the world that enabled researchers to continue with their experiments. This highly public controversy also contributed to the continuing erosion of the legitimacy of the institution of science within society. It also strengthened interest among social scientists in governance and regulatory issues (Wright, 1994). But by the late 1970s, regulatory oversight had become reduced to the management of risk in the laboratory (Gottweis, 1998).

In the early 1980s, leading scientists in the field of genetics began to discuss the possibility of mapping and sequencing all of the human genome, conceived through such metaphors as the Holy Grail, the 'moon shot' of genetics, and most significantly, the book of life. Much of the impetus came from the need to develop better diagnostic and therapeutic tools in the war on cancer, initiated by President Richard Nixon in 1971, with a view to eradicating it by 2015. In 1977, Walter Gilbert in USA and Frederick Sanger in the UK independently developed the gene sequencing methodology which, along with the technique for copying gene sequences (polymerase chain reaction (PCR)), underpinned the Human Genome Project (HGP). PCR was developed by Kary Mullis and the Cetus

Corporation in 1983 and speeded up the sequencing process (Rabinow, 1996a). By 1990 the HGP was officially launched, though some critics argued that straightforward curiosity-driven research was more important, leading Walter Gilbert to assert that possession of the genetic map and DNA sequence of a human being would transform medicine (Gilbert, 1992). The map of the human genome, it was argued, may also provide answers to such questions as the existence of a gene for alcoholism, aggression, or homosexuality, and perhaps even explain the biological basis for intelligence that eluded Francis Galton and the eugenicists. In this way, the biomedical and political systems came together to largely define health and disease, normality and abnormality, presenting genes as causal factors within a reductionist framework (Lippman, 1992). In February 2001, the international, publicly funded Human Genome Sequencing Consortium (in *Nature*) and Craig Venter of the private company Celera (in *Science*) published the first drafts of the full sequence of the human genome.

For social scientists, the HGP provided rich opportunities for investigation and analysis using resources developed mainly in the social studies of science, including social worlds analysis, social constructivism, and actor–network theory. In order for the appropriate funding for the HGP to be accomplished by science, government, and commerce, both in USA and elsewhere, the need to align their different social worlds had to be recognized. This was an example of heterogeneous engineering (Law, 1987) bringing together researchers, techniques, organizations, laboratories, databases, biological materials, funding sources, and political support to the task at hand (Hilgartner, 1995). The HGP became a boundary object – something that serves as an interface between communities of practice (Star and Griesemer, 1989) – allowing the techno-scientific work of mapping and sequencing to proceed by enrolling those from different social worlds, with their differing views about its scientific merit, to agree on a common goal. Much of the work of enrolling allies and translating their interests (Callon, 1986; Latour, 1987) was in the hands of leading spokespersons like Walter Gilbert in USA and Walter Bodmer in the UK, who achieved substantial funding at a time of financial stringency by constructing a doable problem (Fujimura, 1987; Balmer, 1996). The publication of the first maps of the human genome constituted the preliminary attempts to stabilize this technological ensemble of social and techno-scientific elements (Bijker and Law, 1992). It led to genetics moving out of the laboratory and becoming a big science enterprise (Glasner, 2002; Martin, 2001), while still leaving its development and applications in a state of flux.

Science was beginning to lose its authority, and expertise was becoming contested as risks, however real, became recognized as socially located. Experimentation appeared to take place in a global laboratory rather than on someone's laboratory bench (Beck, 1992; Giddens, 1990). A wide range of actors became increasingly involved in co-constructing (Jasanoff, 2004) the trajectory of the emerging technoscience of genomics. Several controversies surrounding the genetic basis of human behavior were revealed to be motivated more by ideology than by science. Lippman (1991) coined the term 'geneticization' to describe how differences between individuals including disorders, behaviors, and psychological variations are reduced to their DNA codes. One example surrounded the publication in 1994 of *The Bell Curve* (Herrnstein and Murray, 1994), which linked intelligence to the class structure in USA. It also implied that African Americans were not as intelligent as their neighbors, adding fuel to the fire of the controversy over race in USA. While presented as such, this was not a work of genetics per se but a secondary analysis of a number of intelligence test studies and social surveys. It revealed a bell curve of IQ, and linked normal variation to such factors as poverty, employment, illegitimacy, and welfare recipiency, mistaking correlation for causality. Social scientists had become involved in the controversy that the book generated, and in related controversies including the genetic basis of race and crime (Carson and Rothstein, 1999).

Within the social studies of science, the study of controversies (Collins, 1981; Nelkin, 1995) developed alongside the analysis of what became known as the crisis of legitimation and the rise of the risk society in late modernity (Habermas, 1976; Beck, 1992). These were often the focus of media attention, with landmarks in the development of genetics taking center stage, from the birth of the first test-tube baby in 1978 to the cloning of Dolly the sheep in 1997. The discovery of the structure of DNA in 1953 was not simply a scientific event, but one that opened new cultural understandings in ways that had previously belonged to the world of fiction (Haran et al., 2008). The image of the double helix became ubiquitous and appeared in many aspects of modern life including advertisements for motorcars and perfumes. It acquired the status of a cultural icon (Nelkin and Lindee, 1995).

In this context, the public understanding of science had become a matter of concern to senior scientists involved in shaping government policies (Royal Society, 1985). In the mid-1980s, as the scientific establishment sought to regain its authority, social science analysis drew on a wide range of disciplines including medical sociology, women's studies, and environmental studies to better understand the processes involved (Wynne, 1995). Underpinning the Royal Society's approach was the widely held view that the main reason for the increasing public concerns about the direction that scientific advance was taking, particularly in the public understanding of genetics, lay in public ignorance about the science itself. This 'deficit model' of public understanding attracted a variety of analyses by social scientists. Wynne and others pointed to the need to better understand the contextualized nature of how the various publics related to scientific knowledge (Irwin and Wynne, 1996) and the importance of recognizing the extent of lay expertise. Rather like the deficit model of public understanding of science, Lippman's geneticization thesis had depended more on the agency of the health practitioners than on the patients and their families (Gibbon, 2002). In contrast, studies were beginning to show that lay people were often knowledgeable about key issues that affected them directly. For example, the ways in which genetic services are used were found to be mediated by differing perceptions of the nature of hereditary conditions within families, and previous experiences of medical interventions (Parsons and Atkinson 1992, Lambert and Rose, 1996). The uptake of prenatal diagnosis provides another example of how, through the narratives of pregnant women, consumers of medical technology become lay experts (Rapp, 2000). Thus, a better understanding of the how lay people are expert in, rather than ignorant of, the ways in which

genetics shapes their lives contributed to discrediting both the deficit model and the geneticization thesis as the completion of the mapping of the human genome approached (Michael, 1992; Kerr et al., 1998).

Current State of Knowledge and Theory

Two key moments inform this section: the completion of the mapping of the human genome to reveal the book of life; and the subsequent discovery that, while extremely valuable, the book itself ignores the importance of epigenetic and other factors in complicating its interpretation. The current state of social science research on genomics is briefly explored along with attempts to provide new conceptual approaches to the study of genomics. There is also a discussion concerning these developments in stem cell research.

The main difference between genetics and genomics is that genetics scrutinizes the functioning and composition of the single gene, whereas genomics addresses all genes and their interrelationships in order to identify their combined influence on the growth and development of the organism. The publication of a final version of the map of the human genome in 2003 and 2004 revealed that, rather than 100 000 genes, it consists of some 20–25 000 genes, significantly fewer than the puffer fish. It also became clear that the concept of the gene was becoming less useful in scientific research with questions raised about the demarcation between one gene and another (Nature, 2006). A greater emphasis was placed on the role of RNA and how cells function over time through the study of epigenesis, or how the interaction between behavioral and genetic factors causes an organism's genes to be expressed in different ways without altering the underlying gene sequence (Moss, 2004).

The promise of the HGP was to improve human health by moving from diagnosis, particularly through identifying single-gene disorders such as cystic fibrosis or Huntington disease, to intervention through gene therapy and pharmacogenomics. The development of genetically based therapies where a disease-causing gene is replaced by a healthy one has made little progress since the first clinical trial in 1990, and the death of Jesse Gelsinger who died of multiple organ failure due to a severe immune response during a trial for ornithine transcarbamylase deficiency (OTCD) in 1999. However, pharmacogenomics appears to have been more successful, though perhaps more through what is promised than through any impact on clinical practice (Hedgecoe, 2004). One of the most common biomedical applications of genetics has been in the area of human reproduction particularly through preimplantation genetic diagnosis where parents with a history of genetic disease can, within clinical settings, select healthy embryos. Such procedures are presented as clear choices for parents to make, but appear in reality to be much more ambiguous (Roberts and Franklin, 2006), and hide the extent to which the social practices of genetics can be said to be eugenic (Shakespeare, 1999). Research suggests that the best types of decisions are made in settings where ambiguity and uncertainty are openly acknowledged by all parties (Kerr, 2009).

The completion of the HGP has generated a vast sea of data raising issues of privacy of information in a variety of contexts including health, insurance and employment, DNA profiling, biobanking, and data sharing. In particular, there are issues relating to whether relatives of carriers of single-gene disorders should have access to this information, or should this information be passed on to third parties such as insurance companies, leading to genetic exceptionalism and discrimination (van Hoyweghen, 2010; Rothstein and Joly, 2009). In the criminal justice system, there has tended to be a reliance on the unassailability and apparent infallibility of DNA data to determine innocence or guilt through DNA profiling (Lynch et al., 2008). The collection of forensic DNA evidence in police-held databases has also been a cause for concern, with data from 0.5% of the population held in USA in CODIS, the Combined DNA Index System, and with 1% in the UK in the NDNAD, the National DNA Database (Nuffield Council, 2007). There are also issues of data sharing between database curators, stakeholders, and users. Often these challenge the competitive nature of research either through possible future commercial application, or, more conventionally, in the publish or perish world of academia. Some of these are addressed through bioinformatics and the ability to retrieve information via online databases. However, there continue to be problems in standardization and cooperation between very locally contingent practices in data generation, management, and regulation (Stein, 2008).

Another focus of concern has been the development of genetically modified organisms (GMOs) and the risks they might pose to the environment, including herbicide resistance, transfer to wild relatives, insect resistance, threat to biodiversity, new viruses and traits, and changes to land use, as well as to the food we eat. The introduction of bioengineered ingredients in processed foods in USA had happened largely without public comment or indeed knowledge (Beckwith et al., 2003). In Europe, and in particular in the UK with a history of food-related health scares, the public has appeared much more resistant (Grove-White et al., 1997). Jasanoff (1995) has argued that the permissiveness of the US response to the introduction of genetically modified (GM) crops is a result of having in place the successful model of an existing precautionary regime for controlling chemicals and other toxic substances. This regulatory model was narrowly prescribed through close agreement between government and industry. The European response, on the other hand, while based on the precautionary principle (Levidow, 2001), was less unitary as countries in the European Union, with very different cultures and histories, responded differentially to the regulatory framework (Levidow, 2009). The introduction of innovatory technologies is thus not a simple linear process dependent on the knowledge of scientific experts, but, according to Jasanoff (2005) a reflection of a society's civic epistemology: how scientific debates are politically framed; how what counts as science is established; and who are the key actors. In India, where GM was introduced in the 1990s, cotton farmers have banded together to forcibly reject transgenic cotton brought in by Monsanto, a US multinational company, burning the crops and exhibiting a civic epistemology rooted in mass local protest within a loosely configured regulatory framework.

Social scientists have developed a number of different ways to theorize the new developments in genomics including concepts such as biosociality and the somatic individual,

expectation and promise, and biovalue and the bioeconomy. Early studies had identified a link between individual genetically based pathologies and social problems (Lippman, 1992). The concept of biosociality (Rabinow, 1996b) was developed to counteract the reductionism of sociobiology by suggesting that new types of group identities and citizenships around shared traits were being created (Rose and Novas, 2004). By appearing at the intersections of between clinical medicine and biotechnology companies, these groups empower their members to influence research agendas rather than be passive recipients. They become ethical pioneers who, as somatic individuals, actively cocreate the interpretation and application of new genetic technologies (Rose, 2007). They create new economies of hope, producing new research agendas and commercial opportunities, thereby breaking with the negative social effects of the earlier eugenic model underpinning geneticization. Recent studies of genomic research using these concepts have been into embryonic stem cell therapy, breast cancer, autism, Parkinson's, and IVF treatment, as well as on the expectations and education surrounding genomic research. The results have covered themes such as novel modes of identity and identification, including genetic citizenship, the role of institutions, ranging from disease advocacy organizations and voluntary organizations to the state, the production of biological knowledge, novel life-forms, and technologies, and the generation of wealth and commercial interests in biology (Gibbon and Novas, 2007).

Genetic advocacy groups need to be involved in shaping future research agendas to fit their particular interests and do so by making clear their hopes and expectations for the directions in which these will progress. However, what constitutes a vision of the future is a contested terrain as many different social and material interests are involved. It can be conceptualized as an object in its own right (Brown et al., 2000). (Many commentators on the new biosciences use the term 'objects' as a shorthand for a wide range of novel biological, social, technological, and regulatory entities.) Futures are created anew as different rhetorical, organizational, and material resources are mobilized including fears of risk and failure. Visions, however, provide a necessary framework, co-constructed between actors and resources, within which decisions about the shape and application of a developing technology can be formulated. In this way, promissory visions have a significant performative value (Brown and Michael, 2003). What appear to be speculative claims about future therapeutic interventions made by pharmaceutical companies and genetic interest groups can be considered fundamental to the process of creating viable sociotechnical networks and make progress. These promissory visions facilitate the enrollment and alignment of key players such as industry (seeking new profits), clinicians (new techniques for treatment), patients (new hope for care), and regulators (new governance frameworks) in establishing a new genetically based medical technology (Hedgecoe and Martin, 2003). As a result, expectations become embedded in novel practices, institutions, representations and inscriptions, and ethics and discourse. In addition to studying genetic advocacy groups (Novas, 2007), studies using this approach have focused on cord blood stem cell banking. Parents invest in storing tissue for possible future use should it be required by their offspring who in the parents' minds are going to be at future risk. The expectation envisaged by these parents is one in which techno-scientific innovation, resulting in therapeutic intervention, and embodied in deposited cord blood samples, becomes technologically feasible (Brown and Kraft, 2006; Martin et al., 2008). In turn interest groups facilitate and encourage their development (Franklin and Lock, 2003).

The attempt through promissory regenerative medicine to add value to life itself suggests that markets exist within which such added value attracts an economic price (Glasner, 2005). Such markets are to be found in global economies related to those of tissues and genetic material. New biological objects with their associated technologies produce genetic capital or biovalue, based on the surplus value that is produced from their extraction and manipulation. Vitality is manufactured in the laboratory (Waldby, 2002). There is a global knowledge economy relating to the flow of ideas and projects, with the publicly funded HGP providing an impressive illustration. Nation-states and global companies outsource their research activities, for example in India through the growth of clinical trials or therapies derived from stem cells, where poverty and ignorance provide willing subjects and regulatory governance is still in a fluid state (Rajan, 2006). Such trials are mainly run by US-based pharmaceutical companies with their Indian partners and are closely colocated with the twentieth century neoliberal capitalist modes of production (Cooper, 2008).

The fueling of bioeconomies through permissive regulation and governance frameworks in areas such as oocyte and embryo donation, and clinical and laboratory applications of stem cell research has a less clearly delineated trajectory than in the more tightly regulated European and US frameworks (Gottweis et al., 2009). The motives of nation-states in encouraging such research may vary widely, sometimes forcing leading scientists to fraudulently announce advances in therapeutic applications. The Korean scientist Hwang Woo-Suk, for example, achieved cult status associated with euphoric expectations of mass healing before his fraud was discovered (Kim, 2008). There are also questions about who benefits and how different public needs are represented, so in India the beneficiaries of stem cell research (as with large-scale clinical trials) are normally to be found elsewhere. However, in some cases, maverick scientists like Geeta Shroff exploit regulatory inconsistencies only for their own patients, and refuse to share their work with the wider scientific community (Bharadwaj and Glasner, 2009). Studies have shown that understanding the practice of how research regulations operate on the ground requires an intimate knowledge of existing modes of social control, the role of the media, and the functioning of local, provincial, and national authorities (see Sleebohm-Faulkner, 2011).

Stem cell banking has been seen as one way in which to ensure that appropriate governance oversight is in place and divert attention away from the more emotive debates that surround stem cell technologies. While a number of private banks are now in operation worldwide, they are often specialist in nature, curating cell lines from adult or cord blood tissue. The first publicly funded bank, the UK Stem Cell Bank, officially opened in 2004 for the deposit of regulated human embryonic stem cell (hESC) lines from approved laboratories, and made the first of these available for wider distribution in 2006. It accepts stem cells, tests them, grows

them, and then distributes them internationally. Through the progressive refinement and purification of persons and materials, the Bank can be seen as a moral refinery providing a visible location for the international legitimacy of hESC science (Stephens et al., 2008).

There is a history of public debates about the ethics and morals of stem cell research using in particular hESCs that has paralleled the discourse of hype and hope concerning future therapeutic applications (Prainsack et al., 2008). This debate, mainly in USA and Europe, has diverted attention from, on the one hand, existing uses of adult stem cells in (for example) bone marrow transplants successful for over 20 years, and on the other, more commercial applications, in (for example) the cosmetic industry. There are two kinds of DNA-based cosmetics. The first uses DNA research to come up with new kinds of ingredients to add to cosmetics, while the second promises to use your genetic profile to create a makeup just for you. Less high profile is the regulatory, manufacturing, and distribution infrastructure that is rapidly being put in place to enable the delivery of near-market human biological products. Here the controversies take a different form, asking questions about when, rather than if, they should come to market, and focusing on how, and by whom, products are considered to be safe (Franklin and Kaftantzi, 2008; Faulkner, 2009).

Some Future Directions

The science of genetics may already, as many commentators suggest, have left the unitary concept of the gene and its linear development behind. The heyday of injecting huge sums of public funding into genomics research is substantially over, being replaced by an emphasis on knowledge translation through privately or commercially funded initiatives. In doing so it has opened a variety of societal avenues of concern, hype and hope including personalized medicine, bioprospecting, biosustainability, human/species enhancement, and bio-weapons development. It has also put into question the accepted boundaries between human/animal, organic/nonorganic, and living/nonliving through the creation of new bio-objects. These include stem cells, trans-species animals, GM crops, or tissues that are cut from human bodies and stored in tissue repositories or biobanks. They are fluid and mobile, allowing discoveries in medicine, for example, to be applied in nutrigenomics and food production. They also challenge current modes of governance through multiple (or even contrasting) meanings as they circulate through different sectors of society. In this way, postgenomics – i.e., the study of the function of DNA and other molecules in the human organism and their interaction with environmental factors – contributes to and simultaneously generates novel social relations (Parry and Dupre, 2011; Vermeulen et al., 2011).

Synthetic biology provides one of the clearest attempts to generate new bio-objects as it attempts the design and construction of new biological parts, devices, and systems, and the redesign of existing natural biological systems for more useful purposes. The greatest success to date comes from the J Craig Venter Institute where, in 2012, a bacterial chromosome was created and was successfully transferred into a bacterium, replacing its existing DNA. The microbial cell then began replicating and producing a new set of proteins (Gibson et al., 2012). However, this was an expensive and time-consuming experiment costing US$40 million and 200 person years, leaving a long gap between its discovery and any future practical or scaled up applications such as artificial biofuels or novel pharmaceuticals. It also rules out immediate uses in warfare or terrorism, although the ethical and governance issues still need to be addressed. Should synthetic biology live up to its hype, it has the potential to shift the boundaries between the natural and the artificial in significant ways.

Another way in which genomics is contributing to making conventional social boundaries more fluid relates to the accumulation, sharing, mining, and integration of data. Following the completion of the HGP, and the development of faster and cheaper ways to sequence and analyze genetic material, researchers are drowning in sea of data. A significant concern has been the archival digital storage of this information with its attendant problems of damage and atrophy. A team from Harvard University has married next-generation sequencing technology with a novel strategy to encode 1000 times the largest amount of data previously stored in DNA (Church et al., 2012). They estimate that it would take only 4 g of DNA to store all human knowledge collected in 1 year, and do so in such a way that, even if lying dormant for millions of years, it would be as accessible then as now. While the cost of DNA-handling tools makes this storage option uncompetitive as yet, and the process is still a slow one, its wider impact has yet to be investigated while the principle has now clearly been established.

The issues of privacy and ownership have become more pressing as the data generated through genetics accumulate exponentially. Historically, the famous case of *John Moore v. Regents of the University of California* in 1990 highlighted the tensions surrounding property rights and profits. Genetic material derived from Moore's spleen (removed as treatment for leukemia) became, without his knowledge or consent, the source of a commercial cell line. Many biomedical research projects are dependent on tissues and data collected from participants and their families. Linking these large, detailed, and heterogeneous data sets enables researchers to generate statistically significant results for use by population geneticists. However, individuals agreeing to participate in biomedical research are normally required to provide informed and voluntary consent for the use of their contribution in these ways. In biobanking, which is now a worldwide feature of postgenomic science, it has proved to be a potentially contentious issue even though its ostensive focus is on the prevention and treatment of disease (Kaye and Stranger, 2009).

As an example of a bio-object, however, the data stored can also be used as a means of reducing costs in health care provision, speeding up drug development and generating commercial opportunities for pharmaceutical companies, and producing personalized therapies for certain disease groups. One by-product of this accessible data is found in Genome Wide Association Studies (GWAS) that compare the genomes of healthy people with the hope of locating genetic variation responsible for common diseases. Such studies are not without their critics as it is clear that GWAS provide data for only a part

of the genetic basis of the human trait. That is, as the US National Institutes of Health (NIH) define them, GWAS only focus on the common genetic factors in populations that influence health and disease. However, human traits consist of more than just genes. Some elements are acquired and we now know could affect how genes themselves are expressed. As a result GWAS are useful only for population-based health studies, and not applicable to individual diagnosis or treatment.

However, GWAS have since 2006 given rise to successful direct-to-consumer genetic testing companies such as Navigenics and 23andMe that are comparatively unregulated and easily accessible via the World Wide Web, raising serious concerns about how informed the users really are (Curnette and Testa, 2012). Biobanks are funded by an equally diverse range of actors ranging from publicly funded hospitals and universities, through pharmaceutical biotechnology and genomics companies, to single-disease advocacy groups. Together these make informed consent in the postgenomic age difficult to manage (Corrigan and Tutton, 2009). However, the generative aspects of bio-objects point to one possible solution through the use of social media to develop participant-centered initiatives in informed consent as the basis for long-term interactive partnerships between patients and researchers or clinicians (Kaye et al., 2012).

The post-HGP landscape of genomics following the demise of the central dogma – DNA makes RNA makes protein – has resulted in a variety of new ways of viewing life, including proteomics, metabolomics, epigenomics, and stem cell biology. The cell rather than the gene is becoming the central actor in biomedical and biotechnical settings once more. In tissue engineering and regenerative medicine, a multidisciplinary field involving biology, medicine, and engineering, new bio-objects abound. The foundation of tissue engineering/regenerative medicine is the ability to exploit living cells in a variety of ways. There are potential therapeutic applications, where the tissue is either grown in a patient or outside the patient and transplanted, restoring, maintaining, or enhancing tissue and organ function. Alternatively, tissue engineering can have diagnostic uses where the tissue is made *in vitro* and used for testing drug metabolism and uptake, toxicity, and pathogenicity. Much of this work is carried out with stem cells data garnered from animal models and applied in areas such as bone tissue, skin, and heart muscle, providing alternatives to organ transplantation (Atala, 2009).

However, studies of how research results are translated from bench to bedside are challenging the accepted rhetoric of a straightforward exchange of new knowledge between the two. The new states of social relations that co-construct the bio-objects of tissue engineering include not only a number of intermediary stages, but also significant differences between those working within them. Between groups, bench scientists differ from clinical practitioners, and proponents of animal models differ from cell biologists, while within groups, there are differing approaches between mouse modelers and primate modelers, or creators of dish cell lines versus those who insist on genetically engineered cell lines. These differences can be analyzed using such concepts as rhetorics of the future, cultural capital and boundary work, to understand the struggle for power between science and medicine in this emerging field (Wainwright et al., 2009).

Conclusion

An international consortium led by the National Human Genome Research Institute (NHGRI) in Bethesda, USA announced the successful completion of the first phase of the Encyclopaedia of DNA Elements (ENCODE) in September 2012. Made up of 32 groups and 440 scientists, it was established in 2003, with a pilot phase completed in 2007. It was the first systematic attempt to work out what the DNA outside protein-coding genes does. At the cost of around US$180 million, researchers have found that 80% of the elements of a human genome sequence have an identifiable function. They have mapped 4 million switches in what was once thought to be junk DNA, and expect that many will help them better understand a range of common human diseases, from diabetes to heart disease, that depend on the complex interaction of hundreds of genes and their associated regulatory elements.

ENCODE research should help guide the hunt for problem areas that lie in the DNA sequence rather than, more conventionally, looking for errors within the genes themselves (ENCODE Consortium, 2012). However, some critics have suggested that the project has been flawed from the start as it uses 50-year-old gene sequences that are known to have significantly altered in makeup. Others have argued that the money would have been better spent on curiosity-oriented and hypothesis-driven research into specific problems, rather than on such an expensive and ultimately open-ended project. ENCODE researchers have responded by making a case for both approaches to complement each other (Maher, 2012). After 40 years, even with a myriad of new discoveries stemming from it, the 1980s debates about whether or not to pursue the HGP have, in the second decade of the twenty-first century, come full circle.

Links

A number of research centers around the globe provide the basis for a growing network of researchers in genetics and society. These together with key genomics Web sites, journals, and book series provide the reader with introductory links to this still-developing subfield.

Centers and Networks

Centre for Biomedicine and Society, Brunel, UK [www.brunel.ac.uk/sss/research/research-centres].

Centre for Society and Genomics, Nijmegen, The Netherlands [www.society-lifesciences.nl/en/home.html].

Centre for Genetics and Society, Berkeley, CA, USA [www.geneticsandsociety.org]

ESRC Genomics Network, UK [www.genomicsnetwork.ac.uk] (this includes three centers and a forum across the UK).

Genome Canada, Ottawa, Canada [www. genomecanada.ca].

Genethon, Evry, France [www.genethon.fr].

National Human Genome Research Institute, Bethesda, USA [www.genome.gov].

The Wellcome Trust, London, UK [www.wellcome.ac.uk].

Journals

BioSocieties: An interdisciplinary journal for the social studies of the life sciences [www.jounals.cambridge.org/bio].

New Genetics and Society. An international platform for informed discussion of key issues raised by the exploitation of the new genetics [www.ingentaconnect.com/content/routledg/cngs].

Science as Culture. Places science within the wider debate on the values that constitute culture; it is not the journal for a particular academic discipline [www.ingentaconnect.com/content/routledg/csac].

Science, Technology & Human Values. An interdisciplinary journal containing research, analyses, and commentary on the development and dynamics of science and technology, including their relationship with politics, society, and culture [sth, sagepub.com].

Social Studies of Science. An international peer-reviewed journal that encourages submissions of original research on science, technology, and medicine [sss.sagepub.com].

Sociology of Health and Illness. An international journal that publishes sociological articles on all aspects of health, illness, medicine, and health care [www.blackwellpublishing.com/shil_enhanced].

Book Series

Cambridge Studies in Genetics and the Life Sciences (Cambridge University Press)

Promotes interdisciplinary works in the social sciences that focus on the social shaping, social meaning, and social implications of recent developments in the life sciences. Interdisciplinary projects will be encouraged with a strong empirical and ethnographic base that explores topics within the context of an internationalized world of science as well as recognizing national variations in ethical, moral, and legal codes and mores [www.cambridge.org/gb/knowledge/series/series_display/item3937957/?site_locale=en_GB].

Genetics and Society Book Series (Routledge)

This series provides an outlet for outstanding scholarship in the multiple fields of genetics and genomics social sciences research. Published with Routledge since 2006, the research monographs, handbooks, textbooks, and edited collections offer authoritative, cutting edge perspectives on issues covering the ethical, legal, social, economic, or political aspects of:

- tissue engineering, enhancement, and cloning
- genetic modification of foodstuffs and other organisms
- neuroscience and neuroethics
- genetic screening and testing
- stem cell research and reproductive technologies
- psychosocial aspects of medical genetics and gene therapy
- the social and ethical issues surrounding biomedical innovation
- public engagement and political discourse
- representations of genetics across the media and cultural spheres
- regulatory policy and governance of biomedical research and its human applications
- the sociology and anthropology of bioscience and biotechnology
- bioethics
- the economics of new biomedical technologies and their place in the 'knowledge economy'

[www.routledge.com/books/series/GANDS].

Health, Technology, and Society (Palgrave Macmillan)

Medicine, health care, and the wider social meaning and management of health are undergoing major changes. In part this reflects developments in science and technology, which enable new forms of diagnosis, treatment, and delivery of health care. It also reflects changes in the locus of care and the social management of health. Locating technical developments in wider socioeconomic and political processes, each book in the series discusses and critiques recent developments in health technologies in specific areas, drawing on a range of analyses provided by the social sciences. Some have a more theoretical, some a more applied focus but all draw on recent research by the authors. The series also looks toward the medium term in anticipating the likely configurations of health in advanced industrial society and does so comparatively, through exploring the globalization and internationalization of health [www.palgrave.com/products/series.aspx?s=HTE].

Abstract

For close to a century, the social and biological sciences have treated the role of biology and genetics in the explanation of human behavior in different ways; while the social sciences have tended to privilege 'nurture' as the cause for variations, biological sciences have leaned toward foregrounding 'nature.' Increasingly, scholars in both fields are viewing the roles of genetics and environment as complementary, a perspective that is also contributing to the breakdown of disciplinary barriers. Contemporary sociologists, for example, often take into account the potential role of genes in analyses of social behavior. This article describes the history of interactions of the disciplines of sociology and genetics and reviews the development of intellectual discourse of the relative roles of genes and environment, highlighting recent contributions by contemporary sociologists.

The controversy surrounding the relationship among evolution, genes, and society has ebbed and flowed over the 150 years since Charles Darwin penned *The Descent of Man* in 1871. Philosopher Herbert Spencer applied natural selection as a metaphor to human society in the mid-1800s, and Charles Darwin himself became embroiled in a debate about whether blacks and whites constituted separate species. (Ethnocentrists of the nineteenth century had sought to use Darwin's concepts to argue for fundamental biological differences between the groups we call races. When Darwin countered these claims, he curiously found himself allied with his one-time foes: the religious conservatives of the day who also argued for the unity of humankind.) Most recently, the revelation that the Beijing Genomics Institute is sequencing the genomes of 2000 individuals with IQs over 150 in search of intelligence genes has led to renewed concerns in the West of an emerging program of eugenics through embryo testing and selective abortion (Normile, 2002).

Part of the reason for such trepidation when it comes to the examination of genetics as it relates to human behavior is that it is commonly assumed that the answers obtained by examining genetics are deterministic ones: to the extent that genes explain any social outcome, this 'naturalizes' any inequality in that outcome. For example, in *The Bell Curve*, Richard Herrnstein and Charles Murray argued that thanks to an ongoing system of meritocracy, today's class stratification is based on innate (i.e., genetic) endowment (Herrnstein and Murray, 1994). Meanwhile, by selectively breeding with others of similar genetic stock, parents reinforce their offspring's advantages or disadvantages. In their view, social policy to promote equal opportunity is counterproductive since each individual has reached the level of social status best suited to his or her native abilities. This is the nightmare conclusion of progressive social scientists and the reason why most avoid genetic data like it was the plague. After all, if all our human outcomes and traits are now increasingly explained by discoveries in genetics and some of our basic social constructs becoming complicated by incorporating findings from genetics and the biological sciences, will the social sciences lose their relevance to understanding human social behavior?

History of Social Science and Genetics

The rise of professional social sciences was partly a response to 'Darwinistic' interpretations of human behavior; that is, human behavior as a product of natural selection. Efforts by scholars like Francis Galton and others to establish a science of eugenics engendered social scientific responses attempting to show the importance of the environment in shaping outcomes ranging from delinquency to class attainment to family relations.

However, the science of genetics never gave up on trying to explore the genetic bases of many human tendencies. During the 1970s a spate of studies emerged suggesting that between a third and half of socioeconomic outcomes could be explained by 'genetic' differences. Even though it was some of their own who authored many of these studies, social scientists wasted no time in questioning both the core assumptions in the models as well as the utility of such estimates themselves. The fire was further fanned by the 1994 publication of *The Bell Curve* which argued that meritocracy had led to the perverse outcome that inequalities were largely based in innate ability – and thus resistant to being remedied by public policy. *The Bell Curve* was, in short order, attacked for its poor methodology and ideological spin. However, the truth is that all of these studies that utilized – twins, adoptees, separated family members, and so on – were really just trying to estimate the size of a black box called genotype without being able to peer inside it. Meanwhile, until recently, no social scientists even bothered to defend the concept of genetic inheritance as a useful datum in the designing of policy.

Recently, however, a new group of sociologists, political scientists, and economists have joined forces with statistical geneticists to make serious arguments about the utility of genetic information to understanding social dynamics

[a] This article is adapted from The Emergence of Socio-Genomics. Contemporary Sociology: A Journal of Reviews 43, 458–467 (July 2014). http://dx.doi.org/10.1177/0094306114539640.

(e.g., Benjamin et al., 2012; Conley, 2009; Fowler and Dawes, 2008). Fast-forward to today and that black box has been cracked by lower-cost DNA genotyping platforms that allow a researcher to actually measure around a half-million or more of the base-pair differences between individuals. The genomics revolution that began in the 1990s ran into some stumbling blocks early out of the gate, however. These included inadequate sample sizes for studies that would search for statistically meaningful effects with hundreds of thousands of discrete 'hypotheses' (i.e., for each marker) and the fact that the markers that were typically measured by the big chip companies (e.g., Affymetrix, Illumina, etc.) were common variants and ignored rarer (and potentially more powerful) sites of difference among humans.

The result of these and other challenges was that these measured markers did not seem to explain the level of variation in outcomes – ranging from schizophrenia to height to IQ – that was meant to be due to 'genetics' according to the prior generation genetic investigations based on twin studies. Slowly but surely, statistical geneticists have made significant progress in solving this 'missing heritability' mystery using a range of newly developed tools. For example, perhaps it was the earlier twin studies that overestimated the role of genes to begin with? That is, the key assumption of 40 years of twin studies is the fact that the estimation of genetic influences rests on the notion that identical twins demonstrate more similar outcomes than do their same-sex fraternal twin counterparts because they share more DNA in common, a notion expressed by the term 'heritability.'

However, plaguing this research is the fact that these twins are probably experiencing more similar environments as well, both because of how others treat them (confusing them, for example) and because they may be closer to each other as well and thus mutually influence each other's choices and experiences than what the fraternal twins do. This 'equal environments assumption' has been the weak link in genetic studies – till now. Now that we have actual DNA markers of twin sets, a natural experiment emerged: Some twins turned out to be wrong about whether they were monozygotic or dizygotic, often because their mothers had been wrongly told by their physicians that the presence of two placentas meant that twins were dizygotic. These 'misclassified' twins allowed us to see if those twins who lived their entire lives as identical but were genetically fraternal (and vice versa) led us to the same results as those earlier studies. That is, if there was indeed any conflating of environmental effects with genetic ones, these misclassified twin sets should tease that out (Conley et al., 2013a). As it turned out, the equal environment assumption of the 1970s held, and the problem of 'missing heritability' – or the extent to which 'genes' explain behavior or diseases – remained unsolved.

Meanwhile, statistical geneticists have developed a number of innovative techniques to address this missing heritability problem. For example, while on average siblings share 50% of their genome, there is significant variability in that figure due to the randomness of recombination and segregation of the grandparental alleles when parents form sperm and eggs. So one pair of siblings may share 45% of their genome while another (even in the same family) may share 60%. By correlating these differences in relatedness among siblings to differences in their outcomes, we are able to generate an unbiased estimate of the genetic contribution to a given trait – that is, heritability (Visscher et al., 2006). Interestingly, those 1970s estimates based on early twin studies now hold up. Using this sibling and other approaches, earlier estimates of heritability were confirmed. And while any individual DNA base (or entire gene for that matter) may not explain much in terms of how we turn out, the sum total of all nucleotide differences did provide a measure of the extent to which genetic variation was predictive of important social outcomes, directly measurable and, to a certain extent, randomly assigned at birth (Rietveld et al., 2013).

At the same time, more and more national surveys were asking respondents to spit into a cup, adding genotype data to the rich tapestry of social variables that economists, sociologists and political scientists had worked with for decades. These additional data may help scientists better understand patterns of human behavior, enhance individuals' self-understanding, and design optimal public policy, especially when the answers we get from peering into the black box are not always – or even often – the kind that reify existing inequalities, assumptions, and policies. As it turns out, adding genetic data to social science upends the apple cart on many of our assumptions. For example, were Herrnstein and Murray right in *The Bell Curve* when they argued that meritocracy has perversely resulted in more intransigent inequalities today because we are now sorted by genetic ability? As it turns out, the data show that thanks to the magic of sexual reproduction – where the deck of genetic cards is reshuffled each generation – genetics does as much (if not more) to upset existing inequalities (i.e., create social mobility) than it does to reinforce social reproduction.

Additionally, a growing body of literature addresses the fluid and complex nature of the creation of individual and collective identities based on genetics and addresses aspects of the commercialization, politics, and regulation of genetic research (see, e.g., Almeling, 2011; Richards, 2013; Nelkin and Lindee, 1995; Conrad and Gabe, 1999; Petersen and Bunton, 2002; Duster, 2013; Hauskeller et al., 2013; Prainsack et al., 2014).

The Role of Environment

So far, we have focused our attention on what new discoveries in genetics can tell us about very thorny issues and ideas in modern society. In general we have neglected a focus on the environment – specifically how environmental factors upend received wisdom about genetic determination and the naturalization of human behaviors and societal structures. However, we now bring the environment back into the conversation and discuss the many complications that emerge. Indeed, genetics and environmental factors seem to interplay with one another in a complex and dynamic feedback loop that begins to explain further several aspects of the behavior of humans and societies – leading to terms and concepts like gene–environment interactions and gene–environment correlation.

One aspect of human behavior that is puzzling is the range of resilience and vulnerability to environmental conditions that we see. Two people (e.g., siblings) who experience the

same negative life event (famine, war, neglect, abuse) can have wildly different outcomes. Additionally, two people with the same genotype (identical twins) often have wildly different life outcomes. These simple observations lead to the (potentially obvious) suggestions that genetics and environments may interact to determine what we see in human behavior – it is not 'nature versus nurture' as much as 'nature and nurture.'

This idea of nature and nurture dynamically interacting and interplaying with one another has also led to various ideas that feed back into our understanding and theorizing in genetics and evolution. An early suggestion was the stress-diathesis hypothesis, where the idea was that some individuals were born with 'risky' genetic variants and others were born with 'safe' genetic variants – but both individuals would have about the same outcomes if placed in a neutral environment. However, if individuals with 'risky' genetic variants were placed in 'risky' environments, we would see disproportionately different outcomes – a gene–environment interaction. Indeed, there is quite a bit of (still controversial) evidence that children who are abused and have 'risky' gene variants related to the serotonin or dopamine systems in our brains experience incredible reductions in life outcomes, while abused children with alternate gene variants are worse off, but not multiplicatively so (Caspi et al., 2003; Conley et al., 2013b; Conley and Rauscher, 2013; Karg and Burmeister, 2011; Risch et al., 2009).

The next question for the stress-diathesis hypothesis, though, comes from an evolutionary perspective – why would humans have 'risky' genetic variants at all, if there were no benefits? Why would evolutionary pressures fail to wipe out these variants? A couple of theories have been proposed. The first set of theories is that these 'risky' variants were, in the not-too-distant past, beneficial. Perhaps the genetic variants that we seem to see producing 'over-reactions' to current stressful environments would have been excellent variants to have in the dangerous Serengeti, and humans are too recently displaced from these environments for the variants to have disappeared through evolution. Or perhaps these 'risky' variants are risky for some outcomes but actually protective for other, often unmeasured, outcomes.

Or … a second theory considers the gene at the level of the species rather than individual and supposes that there are variants that are 'orchids' and other variants that are 'dandelions.' The dandelions do fine in most environmental circumstances, within a reasonable range. However, the orchids thrive in some environments but wilt in others. Again, this is gene–environment interaction, and, at the level of a species, humans would like to have both types of genes in our pool in case of larger changes in the environment (e.g., climate change) that might wipe out all the dandelions and most of the orchids, but allow some orchids to thrive (Conley et al., 2013b).

These theories and the evidence for gene–environmental interactions also potentially have more pressing implications, while we are waiting for evolution to change genotype distributions, we would also like to figure out how the purposeful shaping of our environment that is under human control may affect us. This leads us into thinking about the built environment, schooling, health policies, energy use, and the whole array of government action.

Specifically, we might ask what allows some policies to be effective and others to fail? Many policies are guided by theory and data. We tax products we do not want people to use because economic theory posits a Law of Demand – when prices go up; people consume less of the product. And this theory is often verified by data – when states increase taxes on cigarettes or soda (or whatever), people shift their choices away from these products. We give people housing vouchers to move away from impoverished neighborhoods following sociological and economic theories about the presence of poverty traps and the importance of neighborhoods. However, our policies have a very mixed success rate. Some are successful for some people or during some periods of time but not others. New evidence merging genetics and public policy has started to uncover *why* we see such different impacts of the same policy for different people and how future policies might be targeted – taking the concept of 'personalized medicine' to allow 'personalized policy.'

A case in point is the example of tobacco taxes in the United States. The Institute of Medicine and Centers for Disease Control and Prevention, among others, have ranked this policy as one of the top 10 most impactful on increasing public health in the past century. This is because the United States has witnessed enormous changes in smoking since the first taxes were introduced following the Surgeon General's report in the mid-1960s – which have been cut in half. And raising taxes is cheap for the government, so the benefit–cost ratio is incredibly favorable. But the last decade has seen a reversal. In the face of the largest tax increases in our history, tobacco use has remained virtually unchanged. Has the Law of Demand been repealed? New evidence that combines genetics and social policy evaluation has pointed to an explanation: the pool of smokers in the 1960 was genetically different than the pool of smokers now. People carry around different variants of a group of nicotinic receptor genes with them – and as the name suggests, these genes decide how much dopamine (a pleasure chemical) is released when you smoke; how much you 'like' smoking. These genetic variants also interact with our environments. It looks like many of the smokers in the 1960s did not need a big push (tax increase or social pressure) to quit smoking (or never start). But over time, these small pushes have mostly pushed people to stop smoking if their genes did not put up a big fight. And what we have left in the smoking pool are disproportionately folks whose genes are fighting back, partly because nicotine is so pleasurable. This shows up in evaluations of tobacco tax policy, where only adults with low genetic risk of smoking will still respond to taxation and adults at higher genetic risk seem to be unshaken (Fletcher, 2012).

What does this mean for policy? Should we keep increasing taxes – forcing the remaining smokers to pay a greater and greater share of their incomes in part because they were unlucky in the parental (genetic) lottery of life? Or should we even subsidize their smoking because they love it so much (due in part to their genetics)? Smoking is not the only area where 'personalized' policy may come into play. Evidence has also shown that some educational interventions have greater or lesser effects depending on targeted students' genotypes. Ditto for crime prevention policy. And even the Earned Income Tax Credit spurs low-wage workers to labor more or less depending on their genes. While personalized medicine may be just over the horizon, the potential for custom-tailored social policy is

here today. Whether we want to go down that path is another question altogether.

Genetic analysis not only can inform microlevel analysis of human behavior, it can also add to macrohistorical analysis of social phenomena. For example, a fundamental question in macroeconomics is why some countries have thrived and others have stagnated over the past several hundred years. There has been a revival of interest in this topic in the past few decades and many novel and stark hypotheses have been proposed. Jared Diamond, in a series of books and articles, has suggested that environmental factors that contribute to differences in disease burden, soil efficiency, and similar 'endowments' across countries are a primary source of difference in what we currently see between rich and poor countries. For example, tropical diseases reduce life expectancy in places like Zambia so that trained workers can expect to have only 10 years of economic productivity – the same figure for the United States is over 35 years (Diamond, 1997). Agricultural grain yields in US soil are about 10 times greater per acre than for their African counterpart. And African River Blindness means that Africa is the only continent where populations concentrated *away* from the rivers and coasts, where the most fertile soil is and where growth-stimulating trade is facilitated.

More recently, economists Daron Acemoglu and Simon Johnson and others have dismissed that the environment is a key factor explaining economic success and instead consider the development and expansion of institutions (legal systems, democracy, property rights, corruption, etc.) as the key set of factors explaining why some countries are rich and others are poor (Acemoglu et al., 2002; Easterly and Levine, 2003; Easterly et al., 1993). Some countries arrive at having 'extractive' institutions in which small groups of individuals exploit the rest of the population (think diamond mines in Sierra Leone or Congo) while other countries arrive at 'inclusive' institutions where many people are included in governance (Acemoglu and Robinson, 2012). Key to this argument are examples where geography is held constant but institutions differ. For example, North Korea and South Korea share a peninsula and a microenvironment. The land is of similar quality, the topology of the environment not too different, even the populations are nearly identical. However, a history of inclusive governance in South Korea, and one of noninclusive (extractive) governance in North Korea, Acemoglu and Johnson argue, shines a bright light on the importance of institutions and not geography as the key to development. Think also about the economic performance of East versus West Germany or economic growth trajectories in towns on the US versus Mexico side of the Rio Grande – similar environments, similar people, similar disease burden, but different institutions and different growth and development.

As these new ideas are being sorted out, economists interested in the intersection of economic development, institutions, and geography have begun to explore another aspect of populations that might fit into these grand theories: Population Genetics. In particular, a new breed of macroeconomists has posited that genetic diversity within countries is a key to development. Quamrul Ashraf and Oded Galor published an article providing evidence that an optimum level of genetic diversity within countries might lead to higher incomes and better growth trajectories (Ashraf and Galor, 2013). The authors discuss the observation that there are many countries with relatively low diversity, such as in the Americas, as well as countries with high diversity (e.g., many sub-Saharan African countries) have experienced low economic growth, while many countries with intermediate diversity (such as in Europe and Asia) have been conducive for development in the precolonial as well as modern eras. Basically areas/countries face a trade-off with genetic diversity between cooperation and innovation. The idea is that areas with genetic diversity that is 'too high' have higher likelihoods of disarray and mistrust, which would reduce cooperation and disrupt socioeconomic order and lead to low productivity. However, areas with genetic diversity that is 'too low' might have less innovation, fewer new ideas, and therefore reduced technological capacity. The authors argue that higher diversity "enhances society's capability to integrate advanced and more efficient production methods, expanding the economy's production possibility frontier and conferring the benefits of improved productivity" – an idea motivated by Darwin's theory of evolution by natural selection. These conflicting costs and benefits of genetic diversity lead to the proposition that a 'middle level' of diversity will lead to the highest growth and development patterns. The authors find that, for countries that have low genetic diversity, small increases in diversity (1% point) could increase their population density (a measure of economic development) by 58%; likewise countries with current high genetic diversity who reduced this diversity by 1% point might see an increase in population density of 23%. It should be noted that Ashraf and Galor's premise has been critiqued on a number of fronts, including the fact that a correlation – such as between levels of genetic diversity and economic indicators – does not mean causation (d'Alpoim Guedes et al., 2013).

In addition to considering the 'optimal' level of genetic diversity in populations to maximize economic development, other economists have considered the role of population genetics as it interacts with environmental resources to affect growth patterns across countries. Justin Cook has shown that populations with the (genetic) ability to digest milk after weaning that appeared early in human history conferred large advantages in population density around CE 1500 (Cook, 2013b). As other studies have shown that economic development differences in history have been remarkably persistent, the implication is that (relatively) small changes in the genome, at the right time and in the right place (during the Neolithic Revolution in areas able to raise cattle) can lead to large, persistent, and accumulating differences in economic development across countries.

Macroeconomists have also begun exploring how population genetics might affect economic development through the health of populations that then affect productivity and incomes. For example, Cook has also shown that populations with immune systems that are 'genetically diverse' have had a health advantage in the premodern period (Cook, 2013a). The idea is that pathogens evolve to target specific immune function weaknesses, and populations with limited genetic diversity (and hence limited diversity in immune response) are at particular risk of infectious pathogens spreading and reducing the health of wide swaths of the population. However, at the population level, genetic diversity can be beneficial in inoculating against such widespread health insults

by constraining epidemic spread of illness. Because many pathogens specialize in their attack strategy, populations with multiple defenses (through genetic diversity) can potentially reduce the long run effects of infectious diseases on population health. Indeed, Cook finds that increases in immune genetic diversity (through the human leukocyte antigen system) leads to increases in population (country-level) life expectancies. He then further documents this causal argument by showing that the invention and widespread use of modern vaccinations and other medical technologies has led to a decline in the genetic advantage. That is, modern science and medicine is substituting for 'natural' (genetic) defenses against illnesses – at the population level – and in doing so is promoting convergence in life expectancy, and eventually growth and income, across rich and poor countries. This is another example of gene–environment interactions, at the population level. In earlier times (in diseased environments with lack of medications), genetic variation acted as a buffer against disease – leading to country level differences in life expectancy based in part on genetic differences. But now that the environment has changed, with new medications/vaccinations, the previous genetic advantages have been largely eliminated, so that genes interact with the larger environment in producing outcomes. Likewise, in our earlier example of the 'milk genes,' these genes only confer advantages when in environments which have the ability to foster agriculture. With no cows, goats, or other domesticatable mammals, the gene confers no population advantage.

Conclusion

Until recently, the study of human genetic variation has consisted mainly of behavior genetics studies, where twin and adoption designs were used to identify heritable, or genetic, variation in various traits (see, e.g., Björklund et al., 2006; Plomin et al., 1994; Plomin, 2009; Plug, 2004; Sacerdote, 2007). These studies are controversial and the assumptions underlying them have been questioned (e.g., Goldberger, 1979; for a defense see Conley et al., 2013a; Scarr and Carter-Saltzman, 1979). Whether or not one believes the estimates of genetic influence on phenotypes that emerge from such studies, the fact remains that they do not directly measure genotypes and thus have limited utility for social scientists.

But now, the cost of human genotyping is dropping faster than the rate at which Moore's law is bringing down the price of computer chips (Benjamin et al., 2012), and Americans are genotyping themselves in record numbers using consumer services such as 23andme, AncestryDNA, or FamilyTreeDNA. (In addition to citizen/consumer genotyping databanks, major funding bodies, including those in the social and behavioral sciences, have now begun to incorporate genetic and biological markers into major social surveys. For example, in addition to the pioneering study – the National Longitudinal Survey of Adolescent Health (Add Health) – more recently the Wisconsin Longitudinal Study and the Health and Retirement Survey have released datasets with comprehensively genotyped subjects. Similar efforts are also underway in Europe, for example with the UK Biobank Project in the United Kingdom (Ollier et al., 2005; Platt et al., 2010) and large-scale genotyping of subjects at several European twin registries (Rønningen et al., 2006). These datasets provide new opportunities for asking scientific questions that could not be explored until very recently.) And they, in turn, are acting on the information they receive – as recently demonstrated by Angelina Jolie's preventative, bilateral mastectomy. Meanwhile, genetic data is pouring into what were once purely social scientific studies, raising old debates about genes and IQ, racial differences, risk profiling, criminal justice, political polarization, and privacy. If sociologists seek to remain relevant to the study of human behavior, we must embrace, not flee, this deluge of data. Whether social scientists are interested in modeling gene-by-environment interaction effects to better understand heterogeneity in response to social influences, or, rather, if they merely wish to parse out the genetic effects on behavior in order to gain a less biased estimate of purely social effects, they would do well to integrate genotypic data into their analyses – and ignore it as their peril.

Genetics and the Media

Kate O'Riordan, University of Sussex, Falmer, Brighton, UK

Abstract

Genetics and genomics have been made in the media in significant ways. From the new genetics of the mid-twentieth century, to the Human Genome Project of the 1980s and 1990s to the personal and public genome projects of the twenty-first century, the media has been central. The new genetics ushered in the icon of the double helix and the figure of the heroic genetic scientist. The late twentieth century saw the ascendance of the gene as a powerful cultural trope and the emergence of media genres such as gene-hunting stories and documentary and reality television genres became partners in genetic research. The media became the site of scrutiny and creative intervention in turn of the century anxieties about public engagement with science, and science institutions in turn became more involved in media making. The science–media relationship has seen another shift, from representation to interaction with genomics, and current social media structures are used to enroll publics and research subjects alike.

Since the middle of the twentieth century, genetics has broken with negative associations (eugenics, Nazi science) through the 'new genetics' of the double helix and beyond. These shifts in scientific provenance and reputation have gone hand in hand with media representations of genetics. To a large extent the ascendance of genetics has been coupled with, and facilitated by, increasingly prolific media coverage over the last 50 years. More recently the media cultures of genetics and genomics have shifted from representing and publicizing the icons of genetics to a means by which identities and publics are incorporated into genomics. Examples of this incorporation include reality television genres in which research subjects and patients provide the content for production, and direct-to-consumer genome testing that uses social media structures to enroll and manage media consumers as research subjects.

Representation and Publicity: The Making of an Icon

The new genetics was marked by the image of the double helix (Watson and Crick, 1953) and narratives about its construction. In the late 1980s the 'century of the gene' (Keller, 2002) was being reworked as an era of scientific discovery in health benefits with commercial appeal. Between the 1950s and 1980s the image of the double helix had traveled across so many media forms that it could be said to be iconic. Anthropologist Professor Sarah Franklin argued that it had become a fetish, "Etched on the Western consciousness" (1988).

In the 1990s, Dorothy Nelkin and Susan Lindee (1995), Jose Van Dijck (1998), and Celeste Condit (1999) highlighted the ubiquitous appearance of the gene and its 'mystique' (Van Dijck, 1998) in multiple popular sites, including cartoons, advertising, and lifestyle magazines. One of the aims of their work was to examine the meanings of popular genetics, meanings that are made beyond the control of scientists, research projects, and institutions. Their work signals a strand of media and cultural studies scholarship that intersects with the history and philosophy of science and science communication. An interest in these areas also came to matter for studies in the public understanding of science, public engagement, ELSI (ethical, legal, and social implications) projects and in understanding genetic knowledge. Importantly these scholars also examined the interplay between popular and scientific meanings, concluding that the imaginaries of the gene were powerful, but limited, and both scientific and popular sites needed some kind of 'retooling' of the imagination (Van Dijck, 1998).

Watson and Crick's autobiographical versions of the new genetics (Watson, 1968; Crick, 1988) were media-friendly and news worthy and provided content for books, news, and TV drama in the 1970s and 1980s. The popularity of the story and of Watson's (1968) autobiography was sustained in the making and reception of the British television drama *Lifestory* in 1987. This was a Horizon special science documentary that dramatized James Watson and Francis Crick's construction of the double helix in the 1950s as a heroic discovery narrative. Greg Myers and Sarah Franklin wrote about *Lifestory* in 1988 and 1990. *Lifestory*'s fictionalized version of the work of science, and the vogue for celebrity media scientists ever since, helped to recast genetic scientists as heroic (and sometimes maverick) individuals. In the following decade Jon Turney (1998), Pat Spallone (1993), Jose Van Dijck (1998), Dorothy Nelkin and Susan Lindee (1995), and Donna Haraway (1997) all examined the iconic and fetishistic symbolism of the gene playing out in media cultures.

Despite the iconography of the double helix, media cultures of genetics in the late twentieth century retained some attachment to the darker associations of eugenics and Nazi science. Even as the heroes of modern genetics were being created as media figures, the influential film *The Boys from Brazil* (1978) reminded cinema audiences of the field's associations with evil through a plot linking genetics to cloning and Nazi science. The film constructed a fictional postwar scenario about the cloning of Hitler in secret facilities in Paraguay by Nazi scientists in hiding. The plot supported historical memory of the Second World War, representations of recent scientific cloning advances (Bromhall, 1975), and Joseph Mengele's sanctuary in Paraguay, to intimate that the horror of the film scenario lay in its proximity to the bounds of possibility. The association of genetics with cloning, and thus largely with horror, is one that has continued through media cultures despite the very recent, albeit ambivalent, reworking of the horror of cloning into stem

cell hope. (Haran et al., 2008; O'Riordan, 2012) (This article does not cover all media forms and art and film are notable absences. See Anker and Nelkin (2004) for a review of art in the genetic age and O'Riordan (2012: pp. 71–97) for a discussion of art and genomics. A film and cultural studies analysis of genetics in the cinema can be found in Jackie Stacey's *The Cinematic Life of the Gene* (2010).)

Genes, Genomics, and Media Genre: Celebrity Scientists, Concerns, and Publics

These darker associations were largely reworked as the new genetics of the double helix was consolidated by the advent of the Human Genome Project (HGP) in the 1980s. This project drew intense media attention, as it was represented as heralding a new era of global and public science. A new genre of 'gene-hunting' news stories was instigated which grew in the 1980s and 1990s. These were often linked to humorous examples of pop sociobiology. For example, the opening line of a UK newspaper read:

> A month does not go by, it seems, without some new advance being made in gene discovery. Last week, a team of U.S. scientists published their research in pinpointing a gene for dyslexia. As well as causing Alzheimer's disease, cystic fibrosis and haemophilia, genes have, more controversially, been blamed for predisposing individuals towards shyness, alcoholism and even aggression.
>
> Slater, 1994

The proliferation of these stories, and the ongoing attention to the double helix, the gene, and the institutionalization of genomics led to concerns with this attention and popularity. By the 1990s in the UK there were political concerns about the public understanding of science as a whole, the uptake of genomics specifically, and the beginning of significant research trajectories that would look at the role of the media in relation to these concerns.

The pattern of "the modern, secular, scientific hero" established by Watson (McNeil, 2007: p. 47) as a way of understanding the practices of genetic science has persisted through the HGP and beyond. John Sulston and Craig Venter were cast as the leading figures of this project. This way of figuring celebrity science (McNeil, 2007; Haran et al., 2008; O'Riordan, 2011) continues in the representations of Craig Venter, George Church, Steven Pinker – and most recently – Sergey Brin. Some problems with this particular narrative structure include the erasure of women from representations of science, and an image of science as driven by individual genius, rather than as a complex socially situated set of institutions and working conditions. The scientific hero has become a feature of representations of science, and the celebrity scientist a legitimate figure when crafted appropriately. However, too close an association with celebrity is also used to manage the boundaries of legitimate science and define its limits (Haran, 2007; Haran and Kitzinger, 2009; Gieryn, 1999).

By the late 1990s, multiple sources of scholarship identified the ongoing prominence of positive gene stories in the news (Durant et al., 1996; Nelkin and Lindee, 1995; Nerlich et al., 2002). In fact these gene-hunting stories did not give way to the cures stories that they invoked and concerns about hype also became part of these stories. The public discourse also featured concerns that these stories would mean that biology was understood as genetic determinism, and that eugenics would be ushered in by other means. These concerns were taken up in much of the social research in this area, as well as structuring debates and public engagement initiatives. Debates about whether life could be understood as information, blueprint, or code and whether genetics-enabled deterministic thinking structured much of the turn of the century news discourse (Nerlich et al., 2002; Condit, 1999) although these features were interpreted in different ways. Concerns about race and genetic selection also patterned some of the news stories together with a positive gloss on medical application. In a reworking of concerns raised in Van Dijick's (1995) work, humanities scholar Judith Roof argued that the "hyperbolized notion of DNA" of the new genetics enabled racist and homophobic ideologies, often thought of as historical, to be imported through descriptions of DNA's importance and the image of genomics as a progressive modern science (Roof, 2007). Something of a counter to this argument is Jon Turney's work on genetics in popular culture, *Frankenstein's Footsteps*, which tracks the ways in which nineteenth-century anxieties and negative associations of genetics rather more explicitly haunt the contemporary biosciences (Turney, 1998).

In the policy research around public understandings of science, media institutions have often been attributed blame for generating the hyperbole and for getting the complexity of the science wrong, and this attribution has driven some of the policy agenda around science education and engagement. However, Jenny Kitzinger's work on the reporting of the gay gene offers a challenge to this. "The mass media, in the UK at least, were no more deterministic or 'homophobic' than science journals and were arguably better at locating the research in its social context and discussing its limitations, assumptions and implications" (Kitzinger, 2006: p. 101). Changes in the structure of science journalism, the rise in the importance of publicity for science funding, and the reliance on press releases generated by scientific institutes and journals such as *Nature* also help to generate these features (Bubela et al., 2009). Haran and Kitzinger's work on stem cell science also points to the importance of understanding the contemporary life sciences as mediated science:

> Science and a generically defined "media" are often framed in opposing camps, not least by scientists who blame the media for sensationalism, inaccuracy and distortion …). Rather than accepting the notion of separate spheres (science versus media) it is thus more meaningful to explore the coverage of contemporary scientific advances (and setbacks) as forms of "mediated science" and unpack the role of the media–in our case, primarily the news media–in the "making" of science.
>
> Haran and Kitzinger, 2009: p. 634

The press release has become a ubiquitous feature in science media and often sets the agenda for science news. The completion of the Human Genome Project offers a particularly dramatic example. President Clinton and Prime Minister Blair's joint address in 2000 called publics powerfully into being. The platform of world leaders addressing a global media public

about an innovation in the life sciences, in the name of God and humanity, operated to sediment the "gene as cultural icon" (Nelkin and Lindee, 1995) and to consolidate the metaphor of the book of life, the genome as map and the promise of dramatic medical cures (Nerlich and Hellsten, 2004). In doing so, they also addressed a global genomic public through mass media circulation. Claims of new era marked the address, both state leaders emphasized an ethical, disease-free future in which biotechnology would partner government for the common good of humanity. Since that announcement genomics has shifted again in terms of its address. No longer a single human genome, there is a plurality of national and personal genomics projects, and at the same time genomic publics and audiences have proliferated and become multiple.

Although many genetic variants were identified during the HGP mapping project, the question of what the genome means for its publics has become a more complex question since its completion. In the absence of large-scale medical benefits, cures or discoveries beyond single gene conditions, familiar tropes about ancestry, and forensics came to the fore. Media dramas and factual programming alike saw a proliferation of gene dramas based on these themes. The biggest single media project was National Geographic's *Genographic Project* (2005). National programming about ancestry, paternity, race, and identity such as the *Face of Britain* (2007, UK), which popularized Walter Bodmer's population genetics, have continued. The *Genographic Project* championed the work of geneticist Spencer Wells, and its reach and impact in popularizing genetics as an epic ancestry project has been significant. It epitomizes a popular genre in the media cultures of genetics where reality or documentary forms enroll research subjects and genetic research is used to frame and narrate identity.

The promise of public health benefits coupled with commercial application persists as the dominant framing for the significance of genomics. However, the figure of the celebrity scientist has become supplemented by the vision of multiple public participants in genome sequencing. *Genomics England*, a national genome-sequencing project in the UK funded from the National Health Service, was launched in 2013 the basis of this vision. However, as well as legitimizing genomics, publics are also positioned as a potential threat, or an antipublic, represented as either too interested or irrational or religious to be good genomic publics. These constructions of dangerous publics threaten to exclude the legitimacy of some people by assigning them as irrational, having a special interest, or as a 'lobby' (Haran et al., 2008). These exclusions generate a form of media address where those who are not on the side of the progress narratives of genomics threaten the (public) benefits of genomics, where activist mobilization is not encouraged, while purchasing genome tests and joining genome projects is endorsed. The appeal to consumer publics and the rejection of agonistic publics constructs genomics as a form of consumption.

Twenty-First Century Media: Interactivity and Mediatization

Genomics is an informatic science that generates more data than can be searched or used on a human scale. Algorithmic structures and computer delegated storage, search, and hypothesis are requirements in contemporary genomic science. These interface directly with Internet media structures and the same conditions – market-led, consumer public uptake, user-generated content, crowd sourcing, and data visualization – come together in both media cultures and genomics. Companies like *23andMe* and initiatives such as the *Personal Genome Project*(s) instantiate this coming together: where to be a user, audience, or subject of genomics is to be a user, audience, or subject of digital media forms.

Since the HGP then there has been a shift in the kind of address made by the media. The completion of the HGP came together with the mass consumption of social media, and mediatization (Krotz, 2008), where media become ubiquitous and aspects of everyday life are mediated. If media audiences were asked to marvel at the iconography of the gene in the 1980s and 1990s and were regaled with gene-hunting stories, twenty-first-century media cultures change the mode of address. Digital media cultures of genomics invite audiences to interact directly with genomics, incorporating it into embodied practices. Rather than watching others become research subjects in the reality TV and documentary mode, digital culture demands participation. This shift from iconography to interactivity does not necessarily escape earlier questions about the quality of public genomic knowledge but it changes how knowledge is made.

The current mode of address in genomic media has also shifted from foregrounding life to foregrounding death. Genomics on a mythic scale is attached to the meaning of both life and death (Keller, 1992). However, the attachments to life, life stories, and books of life (Kay, 2000) that characterized the ascent of the genome have also seen an attention to death. Genome sequencing and genotyping was variously articulated in the UK as 'the doomsday test,' The Killer in Me, 'how will I die?' 'can I take the worst?' in a range of newspaper and television appearances around 2007.

Direct-to-consumer testing, personal whole genome sequencing–projects, and national sequencing initiatives have emerged as media forms. Audiences are addressed as though they can personalize the genome and interact with it. Genomics may be the book of life but the mode of address is to 'know thyself' (Knome Inc.). Audiences are now asked to identify with and narrate a version of 'my genomic life' (Pinker, 2009) and in this transition, in this context, the facts of life now also appear as the realities of death.

Media Futures

The incorporation of research subjects and publics through social media and other digital media forms seems likely to continue. Internet media are showing no signs of going away. These communication technologies as a feature of all kinds of knowledge production, including science, continue in ascendance. Examples of the current media cultures of genomics that have emerged from this genomics/media nexus, and which might point to future developments, include life logging, data tracking, big data, and the Quantified Self.

Genetics, Disease, and Reproduction

Abstract

This entry overviews the literature on genetics, disease, and reproduction, with a focus on what genetic diseases mean for people within their reproductive lives. The focus will be on the different technologies used to both assess and ameliorate these disorders at different stages of reproduction; the ways a genetic disease is understood and acted upon are thus shaped by biological time. For example, preimplantation genetic diagnosis is generally used to avoid giving birth to a child with a heritable disorder that will result in death within the first couple years of the child's life. Meanwhile, newborn screening is used to assess for the presence of a heritable disorder that can be ameliorated if treated early. As such, different social, ethical, and legal issues are raised within the varying reproductive contexts within which heritable diseases are both detected and treated. But in addition, the meaning of these techniques varies across different national and regional contexts.

The Human Genome Project (HGP) was hailed as a means to find the genetic causes of a full range of diseases, an assumption that tightly coupled genetics, disease, and reproduction through heredity. It was assumed that this would enable new treatments for genetic disorders, particular gene therapy. However, the completion of the HGP has somewhat ironically shown this to be a simplistic understanding of disease; an era of postgenomic thinking has been ushered in, wherein genes are not viewed as deterministic but are instead understood as parts within systems and processes (Chilibeck et al., 2011; Lock, 2005; Keller, 2000, 2010). In addition, the HGP has probably been more significant to date in helping to create tests for the *diagnosis* of mono- and polygenetic disorders rather than in the *treatment* of these diseases (e.g., via gene therapy). As a consequence, the HGP has had significant impacts upon reproductive medicine, where more genetic tests have been introduced than in any other area of health care delivery in order to screen for, rather than treat, heritable disease (Pavone and Arias, 2012: p. 236). Assessing and acting upon the risk of genetic disorders have thus become an increasing focus in reproductive medicine.

This entry reviews the social science literature on genetics, disease, and reproduction with a focus on what genetic disease means for people within their reproductive lives. I consider the social science literature that explores the different technologies used to both assess the risk for and ameliorate genetic diseases at different stages of reproduction. This includes prenatal genetic diagnosis, preimplantation genetic diagnosis (PGD), newborn screening, and genetic testing later in life. Taken together, this literature shows that the ways a genetic disease is understood and acted upon are informed by the temporal, social, and biological ordering of reproduction. For example, PGD, in which embryos produced through *in vitro* fertilization (IVF) are assessed for heritable diseases before implantation, was initially developed to avoid giving birth to a child with a severe illness that would result in a painful and premature death (Franklin and Roberts, 2006). Meanwhile, newborn screening was initially developed to screen for a heritable disorder that could be treated if detected early in life (Paul, 1998a). As such, different social, ethical, and legal issues are raised within the varying reproductive contexts in which genetic diseases are both detected and addressed.

A key contribution of social science research on genetics, disease, and reproduction has been to explore the social, economic, political, historical, and cultural contexts that shape reproductive decision making in the context of genetic disorders. Here, scholars have asked how clinicians and parents alike confront the dilemmas raised by these techniques. Because reproductive technologies are here used to select against genetic disorders, these techniques necessarily raise questions and concerns regarding the delineation of the 'normal' body (Vailly, 2008) and corresponding eugenic consequences for those deemed 'abnormal' (Duster, 1990). As a consequence, these techniques have, in some parts of the world, been heavily criticized by disability activists (Parens and Asch, 2003; Shakespeare, 1998, 1999). In addition, reproductive and genetic technologies have been resisted on religious grounds, particularly as a result of abortion opposition (Evans, 2010). A common theme across this literature is that parents and clinicians have had to become what Rapp (2000) has called 'moral pioneers' in adjudicating different responsibilities while assessing, using, or rejecting innovative reproductive technologies to avoid or treat genetic disorders (see also Kalfoglou, 2005; Franklin and Roberts, 2006; Williams et al., 2005).

Scholars have characterized moral pioneering as emblematic of the more widespread individualization and privatization of risk assessment in social life (Kerr, 2004; Hallowell, 1999 Helen, 2010; Williams et al., 2005), as part of the 'responsibilization' and 'ethicalization' of subjects in neoliberalism (Helen, 2010; Rose, 2007). However, as social science research has expanded to consider genetic testing and reproductive medicine beyond urban centers in North America and Western Europe, social scientists are increasingly finding that these techniques are differently constitutive of social life when used in varied political, economic, historical, cultural, religious, and national contexts (Prainsack and Siegal, 2006; Hashiloni-Dolev and Shkedi, 2007; Kelly, 2009; Ivry, 2006; Ettore, 2002).

Testing for Genetic Diseases in Utero: Prenatal Genetic Diagnosis

Much of the research in social studies of reproduction, genetics, and disease focuses on prenatal genetic diagnosis. This includes noninvasive tests such as blood tests for genetic mutations as well as assessing nuchal thickening through ultrasound. These

screens provide risk ratios, which indicate if more invasive, diagnostic tests should be conducted including amniocentesis and chorionic villus sampling. If the test indicates the fetus has a genetic disorder, the pregnant woman and, if applicable, her partner must decide if they will abort. Amniocentesis was originally used to detect Down syndrome amongst pregnant women 35 and older, but prenatal screening has expanded significantly since. Many countries now offer all pregnant women screening for a range of genetic disorders (Williams et al., 2005; Vassy, 2006).

In her now canonical multisited ethnography of amniocentesis, Rapp (2000) interrogated the ways in which different groups of patients and professionals use and understand amniocentesis in New York City. She situates amniocentesis within the historical processes of eugenics, feminist social movements rooted in reproductive choice, disability activism, unequal access to health services in the United States, and scientific developments in the area of genetics. Drawing on Colen's (1995) concept of stratified reproduction, Rapp illustrates the diversity of women's experiences with this technique and the corresponding question of whether or not to abort. She shows that the decision-making process is structurally delimited according to race, ethnicity, class, migration status, and religion. Rapp has since gone on to show how prenatal genetic testing is a form of 'flexible eugenics,' one that is rooted in neoliberal choice as opposed to state and professional mandates (Taussig et al., 2003). But she emphasizes that these choices are made within the socially structured constraints of women's everyday lives.

Social scientists have since explored the ways in which women outside the United States understand and experience prenatal genetic testing, allowing for comparisons of varying practices across different national contexts. In the United Kingdom, Ireland, and Iceland, scholars have explored women's experiences with the expansion of screening beyond high-risk groups to include the general population with tests that occur in the first rather than second trimester, also noting the ambivalences that women have regarding this information and the kinds of choices it enables (Williams et al., 2005; Gottfreosdottie, 2009; Lalor et al., 2009). Meanwhile, scholars have also expanded their analyses to consider men's experiences with genetic testing (Inhorn et al., 2009; Ivry and Teman, 2008; Reed, 2009). For example, where Rapp finds husbands were at times controlling, Reed's (2009) later research in the United Kingdom finds that women experienced their husband's involvement as supporting. Research in Israel similarly shows that women use or refuse prenatal screening in ways that negotiate diverse social and cultural terrain including religious beliefs, perceptions of support for disabled children, a sense of what counts as good mothering, and trust in physicians (Remennick, 2006). But there is overall a great deal of support for prenatal genetic testing in Israel that has been linked to the dominance of the medical profession (Remennick, 2006), bodily ideals related to Zionism (Weiss, 2002), and biocultural notions of life (Hashiloni-Dolev, 2006). Researchers have also found support for prenatal screening amongst disability activists in Israel, which contrasts with the United States and Western Europe (Raz, 2004). This is because disability activists see testing and abortion as a distinct issue when compared to ensuring social support for disabled people after birth. In contrast, social science research in Japan has found that prenatal genetic diagnosis, and the corresponding geneticization of prenatal care, is being actively resisted by health care professionals (Ivry, 2006).

Prenatal genetic diagnosis is organized so as to position women and their partners at the center of reproductive decision making through nondirective counseling. This shifts responsibility from the medical profession and state to women and their partners, which in turn distances prenatal genetic diagnosis from early twentieth-century eugenic programs (Kerr et al., 1998; Williams et al., 2002c; Paul, 1998b). Social science research in the United Kingdom has shown that the majority of health professionals support the idea that women should be allowed to make these decisions (Williams et al., 2002a,b; Farsides et al., 2004). However, this research also finds that some health professionals question if there should be a line drawn. That said, these health professionals were also aware that how to draw such a line is difficult, raising questions about what counts as a normal versus pathological, or mild versus severe, condition that frequently lack consensus (Williams et al., 2002b). Social scientists working in the tradition of disability studies have emphasized that people living with these conditions should be involved in such deliberations (Shakespeare, 1999), and that social science research on reproduction, genetics, and disease should include within its purview parenting children with disabilities (Landsmen, 2003). In turn, while early research found that clinicians failed to appreciate the structural conditions in which decisions about having a disabled child are made (Kerr et al., 1998), Williams et al. (2002d: p. 747) found that many of the health care workers they spoke with in the United Kingdom were troubled by the ways in which stigma surrounding disability along with structural constraints shape decision making.

Nondirective counseling is the primary technology through which reproductive decisions are made in the context of prenatal genetic diagnosis (Pilnick, 2004; Williams et al., 2002c; Paul, 1998b). There are, however, questions about the extent to which counseling can be nondirective, as research indicates that offering prenatal genetic diagnosis is often interpreted by women as an endorsement of the technique and the perception of it is routinization (Pilnick, 2004: p. 456; Williams et al., 2002c,d). As a consequence, some women are not aware that they are actively choosing to use these tests (Press and Browner, 1997). And miscommunication in the context of cultural and linguistic differences can create further barriers to nondirective counseling (Browner et al., 2003).

Testing for Genetic Diseases *In Vivo*: PGD

PGD builds upon and extends the use of IVF to treat infertility in order to alternatively avoid conceiving a fetus with a heritable disorder (Franklin and Roberts, 2006; Ehrich and Williams, 2010). The embryos created through IVF are tested for chromosomal indications of a disorder, and only those embryos not at risk are transferred back to the woman for gestation. As such, PGD allows women and couples to test for a heritable disease before pregnancy so as to avoid termination.

Due to the relationship between genetic abnormalities and advanced maternal age, PGD is also used to test for chromosomal alterations and aneuploidy so as to improve the chance of pregnancy using IVF amongst women over 35. The technique has expanded to include the creation of 'savior siblings.' Here, embryos are selected both to avoid a genetic disorder and for tissue matching, so that the resulting child could serve as a cord blood or bone marrow donor to another child suffering from a heritable disease (Hashiloni-Dolev and Shkedi, 2007: p. 2081; Devolder, 2005). And there are ongoing debates over the use of PGD for social sex selection.

Different countries have implemented different policies surrounding the use of PGD. Social science research has, on the one hand, examined the reasons for this variation. A significant amount of research has focused on Germany's resistance to PGD in comparison to regulated support in other national contexts within Europe (Krones and Richter, 2004; Meister et al., 2005; Hashiloni-Dolev and Shkedi, 2007). Surveys indicate that this is a reflection of the political culture of Germany as opposed to the general public's attitudes and opinions (Krones and Richter, 2004; Meister et al., 2005). Similarly, in considering the rapid expansion of PGD in Spain when compared to other permitting countries like the United Kingdom, Pavone and Avias (2012) have emphasized the importance of political economy in delineating varied policies. They explain this diffusion through the expansion of private IVF centers in Spain that cater to medical tourists, combined with the slow implementation of regulatory oversight. Meanwhile, Hashiloni-Dolev and Shkedi (2007) have compared German opposition to PGD for sibling donation with support in Israel, a country that is known to be very supportive of reproductive and genetic technologies. They argue that the difference between these two national policies is rooted in different family ethics, particularly different belief systems regarding familial obligations. They contend that German beliefs that parents should unconditionally love their children as individuals inform concern that PGD could be exploitative, whereas Israeli understandings of the family as a mutually dependent unit inform the support for PGD as a means for siblings and parents to help one another as part of a unified body. In doing so, Hashiloni-Dolev and Shkedi emphasize the cultural as opposed to the political economic in explaining national differences with regard to PGD regulation and use.

Within much of Europe, the popular discussion of PGD has been framed by the idea that parents are trying to 'design' and 'perfect' their children by using this technique. Some areas of social science scholarship have expressed similar concerns. Habermas (2003) has, for example, argued against PGD on the basis that parents, in making such choices about their child's life, restrict their child's freedom to become a unique individual. Meanwhile, much of the social science literature has alternatively sought to understand the experiences of parents who decide to use PGD (Franklin and Roberts, 2006; Kalfoglou, 2005). Franklin and Roberts (2006) conducted one of the first ethnographic studies of PGD in the United Kingdom, which included both observations and interviews within clinics as well as qualitative interviews with would-be parents in their homes. Countering the frames of 'design' and 'perfection,' Franklin and Roberts instead show parents who have either suffered multiple miscarriages or lost a very young child to a very painful death as a consequence of a heritable disease. Some women had undergone one or more terminations after tests showed that the fetus carried genetic markers for a disorder that they had already seen a child or loved one suffer from. In this context, parents had to continually make a number of complicated decisions within the uncertain trajectory of both IVF and PGD, where success rates are low.

Building upon this research, social scientists have also explored PGD and IVF staff perceptions and experiences with this form of genetic testing. Contra the polarized debates in the United Kingdom, research has found that staff have rather divergent, conflicted, and ambivalent feelings about embryos and PGD (Ehrich et al., 2008, 2007; Williams et al., 2007). This is because decisions are rarely clear-cut. For example, should a couple select against embryos that are unaffected or should they also select against embryos that are 'carriers' (e.g., embryos that will result in a healthy child who could nonetheless pass the genetic mutation to their children)? The latter could be seen as a stronger form of eugenics, as it goes beyond ridding the disease from the next generation to ridding the disease into the future (Shakespeare, 1998). Ehrich et al. (2007) found that staff members within UK PGD and IVF clinics held very different opinions when addressing this question in weighing the individual versus societal ramifications of the technique.

PGD has begun to raise new questions and dilemmas as its use has expanded from severe genetic disorders with high penetrance that result in the death of young children to include chromosomal abnormalities with lower penetrance, with an uncertain prognosis, and that affect adults (Williams et al., 2007; Kalfoglou, 2005). Research has found that providers in both the United States and the United Kingdom are less supportive of these developments, and express a range of opinions (Kalfoglou, 2005; Williams et al., 2007). The expansion of PGD for sex selection also raises new kinds of questions. While currently illegal in the United Kingdom, Ehrich et al. (2007) report that staff generally looked upon such developments unfavorably but nonetheless struggled with the fact that they had to withhold information regarding sex from a woman or couple who would later terminate a pregnancy as a means of sex selection. Scully et al. (2006) find the public in the United Kingdom to also be ambivalent about choice in the context of social sex selection. Meanwhile, in the United States, many PGD providers will not provide social sex selection even though it is permitted. In this regulatory context, however, some providers are more willing to provide information about sex in the context of using PGD for medical purposes (Kalfoglou, 2005).

By raising the dilemmas involved in actually using PGD, the social science literature has reassessed key ethical categories like 'autonomous choice' (Zeiler, 2004; Ehrich et al., 2007), individual versus social consequences (Ehrich et al., 2007, 2006), 'serious and significant risk' (Williams et al., 2007), as well as 'quality life' (Ehrich and Williams, 2010; Wahlberg, 2008). This research has found that such distinctions are rarely clear-cut in clinical practice, but must instead be actively managed within social, cultural, and institutional contexts. What makes these negotiations different from those that occur in prenatal

diagnosis is that women or couples come to PGD after having experienced firsthand the heritable disorder in question (Williams et al., 2007; Franklin and Roberts, 2006). In addition, the moral status of an embryo is often viewed as different from the moral status of a fetus (Williams et al., 2007), although in Germany this has had the somewhat ironic consequence of permitting termination while outlawing PGD (Krones and Richter, 2004).

Testing for Genetic Diseases upon Birth: Newborn Screening

Many parts of the world either offer or mandate newborn screening to detect heritable disorders that can be ameliorated if treated early in life, before symptoms appear (Raho, 2008). Newborn screening was initiated in the United States during the 1960s for the disease phenylketonuria (PKU). Here, a defect in a liver enzyme results in an inability to metabolize phenylalanine, which generally results in retardation as a consequence of accumulating toxic levels of the amino acids through normal dietary intake (Paul, 2008: p. 8). With the creation of the Guthrie test, wherein a newborn's heel is pricked so that a few drops of blood can be placed on a filter paper for an assay, newborn screening for PKU became universal in the United States between 1967 and the mid-1970s. Newborn screening continues to be mandatory today, which means that it is largely practiced without informed consent. This creates a significant amount of shock on the part of new parents who receive a positive diagnosis shortly after their child is born (Grob, 2008; Timmermans and Buchbinder, 2010). However, proponents of newborn screening for PKU have successfully argued that this problem is offset by the ability to treat afflicted newborns with diets that lack phenylalanine, thereby averting mental retardation. Mandated newborn screening continues to be justified according to this argument.

The number of disorders assessed by newborn screening has expanded significantly, a process that accelerated with the introduction of tandem mass spectrometry (MS/MS) in the 1990s. In 2005, the American College of Medical Genetics issued a report advocating for this expansion; by 2009, 44 states tested for all 29 recommended conditions while six screened for 21 of the 29 (Timmermans and Buchbinder, 2010: p. 408). While MS/MS has led to an expansion in the number of disorders being universally screened for in the United States, it has also led to an increasing number of countries legally mandating newborn screening worldwide (Raho, 2008: p. 1).

To date, much of the social science research on newborn screening has focused on its development and use within the United States. Diane Paul (2008, 1998a) historicizes the development of newborn screening in the United States, showing that its uptake for PKU was contentious amongst metabolic researchers and clinicians for a number of reasons, including lower disease incidence rates than those publicized; a lifelong (as opposed to 5-year) treatment requirement comprising expensive, difficult-to-prepare, and bland food; as well as high numbers of false positives that resulted in children being unnecessarily deprived of nutrients (Paul, 2008: p. 9, 1998a). Paul shows that patient advocacy groups as well as profit-oriented medical companies have increasingly come to play a significant role in the development of this health care policy (Paul, 2008, 1998a). In the process, Paul highlights that the admittedly worthy goal of treating newborns before they become symptomatic is not as straightforward in practice as is frequently represented by advocates.

Social science research has since empirically explored the dilemmas that arise when newborn screening is implemented. Timmermans and Buchbinder (2010) have, for example, shown that diagnosing and treating a newborn based on genetic information garnered from MS/MS are not always straightforward. Based on their ethnographic study in a California clinic, the authors explore 24 (out of a total of 55) cases in which the results of the screen were ambiguous. Timmermans and Buchbinder refer to these newborns and their parents as 'patients-in-waiting.' When test results are ambiguous, the newborn is treated as if he or she has a serious condition. This has consequences for parents. Specifically, Timmermans and Buchbinder find that, in instances when geneticists come to believe the condition is not serious due to subsequent tests and events, almost all parents nonetheless experienced sustained levels of extremely high concern for their child's health. Timmermans and Buchbinder's discussion of these dilemmas has reignited debates with proponents of newborn screening, who have seen this 'critical' perspective as a disservice to public health as opposed to an opportunity to work through the uncertainties that arise when implementing innovative medical technologies (e.g., Timmermans and Buchbinder, 2011; Watson et al., 2010).

Timmermans and Buchbinder (2010) emphasize that patients-in-waiting occupy a liminal, or ambiguous, space between normalcy and pathology in clinical medicine, which results in a lengthy period of medical surveillance. Rachel Grob (2008) follows the ways in which parents experience this liminal space outside of the clinic, in their family life. Grob conducted qualitative interviews with parents of children diagnosed with cystic fibrosis prenatally ($n = 4$), via newborn screening ($n = 16$), or after the development of symptoms ($n = 11$). Like the patients in Timmermans and Buchbinder's study, some parents in Grob's study also had to confront the ambiguity of genetic mutations that may not result in the child ever becoming symptomatic. Also like Timmermans and Buchbinder, Grob found that receiving the diagnosis via newborn screening affected the relationship between parent and child. Where Timmermans and Buchbinder focus on the concerns of illness when these worries are no longer viewed as medically founded, Grob alternatively finds that parents come to be actively involved in the medicalization of newborns. She points out that parents learn about their child in tandem with learning about cystic fibrosis (Grob, 2008: p. 1059). Receiving this information when one is in the early stages of learning how to parent led many to view physicians as the experts of their children's well-being. That said, Grob (2008: p. 1061) did find that parents over time became more confident and assertive advocates for their children.

Social science literature on newborn screening has thus emphasized the ways in which medical and scientific uncertainties surrounding the genotype–phenotype relationship become acutely felt in the practices of newborn screening, particularly by parents but also by clinicians who are uncertain of how to best treat potential patients.

Testing for Genetic Diseases Later in Life: Reproductive Decision Making

One of the rationales for using newborn screening to detect disorders that lack a cure has been to provide parents with information that will assist them with their reproductive decision making (Paul, 2008: p. 11), which will presumably have cost-saving implications for the state (Grob, 2006: p. 162). The ways in which genetic testing is used to inform reproductive decision making have similarly expanded as genetic tests are used to assess susceptibility for genetic disorders that present later in life, such as Huntington's disease (Taylor, 2004: p. 141; Konrad, 2005), breast cancer (Hallowell, 1999), and Alzheimer's disease (Chilibeck et al., 2011; Lock et al., 2006). This intersects with the development of community genetic programs that have been used to determine if couples are carriers of genetic disorders in communities that experience a high prevalence of a disease. Here decisions about whether or not to reproduce are made through the prism of susceptibility for having children with a heritable disease.

Due to a high rate of endogamy, a possible founder effect, and genetic drift, the incidence of heritable diseases is higher within Ashkenazi-Jewish communities (Prainsack and Siegal, 2006). After having four children die from Tay–Sachs, New York Rabbi Joseph Ekstein developed Dor Yeshorim, a community genetics program, in the 1960s. This is a system in which couples are assessed before marriage to find out if they are 'genetically compatible' (Prainsack and Siegal, 2006; Raz and Vizner, 2008; Wailoo and Pemberton, 2006). Here individuals are tested when they are teenagers. However, because of concerns that the entire family of a known carrier would be stigmatized, individual genetic tests are not given at this time. Rather, once a marriage between two people is being considered, Dor Yeshorim will report whether or not the couple is at risk of having children with a heritable disease. If the couple is not genetically compatible, the marriage is generally called off. Prainsack and Siegal (2006) emphasize that this testing system works because arranged marriages are commonplace, and so compatibility is assessed early in the marriage process and quite possibly before the couple has even met. They contrast this with the community testing program for thalassemia in Cyprus, where individuals learn of their own results and marriages continue despite 'genetic incompatibility' with an indication that prenatal genetic screening should be used.

In the general population, hereditary disorders are also likely to have consequences for the wider familial unit once detected (Lock et al., 2006; Finkler et al., 2003; Chilibeck et al., 2011; Konrad, 2005). This includes not only couples but also their siblings. For example, social science research has explored how couples make reproductive decisions after having a child diagnosed with a heritable disorder (Kelly, 2009; Raspberry and Skinner, 2011a,b). Both Kelly (2009) and Raspberry and Skinner (2011a,b) find that parents make a range of different decisions prenatal in this context, including not having more children, using prenatal diagnosis or PGD, as well as having additional planned and unplanned children in an unmediated manner. However, both studies found that the majority of participants decided not to have more children. Social science research has also explored if and how people disclose the presence of a heritable disorder to their wider family (Konrad, 2005). Questions regarding responsibility and autonomy are particularly acute here, as some siblings may or may not want to consider their genetic risk as part of their family-planning practices (Liao, 2009; Arribas-Ayllon et al., 2008a,b; Hallowell et al., 2006). For example, while some women would certainly want to know this information (Liao, 2009), many of the rural women that Kelly (2009) interviewed in the United States actively choose not to make the kinds of choices that such knowledge necessitates. Disclosure would have made it impossible for these women to 'choose not to choose.'

Conclusion

The ways in which a genetic disorder is understood and acted upon is informed by the social, temporal, and biological ordering of reproduction. Most of the techniques used to assess for genetic disorders are screens rather than treatments. Nonetheless, different screens are informed by and enable different kinds of reproductive trajectories. Prenatal screening and diagnosis offer women and their partners the choice to abort a fetus with a chromosomal disorder. PGD offers women and their partners the ability to select out embryos that have a heritable disease. Meanwhile, genetic testing later in life enables women and their partners to ask if they will have children at all, and if those pregnancies will be medically mediated or not. Newborn screening is the only genetic test that is associated with therapeutics. However, it nonetheless raises many uncertainties and ambivalences that social scientists have consistently found in personal and professional accounts of genetic screening.

In this context, women and their partners have had to become 'moral pioneers' (Rapp, 2000), adjudicating different responsibilities in the context of political, economic, social, cultural, historical, and religious constraints. This process has been linked with the increasing individualization, 'responsibilization,' and 'ethicalization' of subjects in neoliberalism (Helen, 2010; Rose, 2007). However, as social science research has expanded to consider genetic testing and reproductive medicine beyond urban centers in North America and Western Europe, social scientists are increasingly finding that these techniques are varyingly constituted in different places (Prainsack and Siegal, 2006; Hashiloni-Dolev and Shkedi, 2007; Kelly, 2009; Ivry, 2006; Ettore, 2002). Rural women in the United States reject the notion that one needs to know about the genetics of their fetus in order to be a responsible mother (Kelly, 2009). Japanese Ob–Gyns resist the use of prenatal genetic tests, emphasizing gestational responsibility (Ivry, 2006). And the priority of the family over the individual leads to different notions of what responsible parenting entails in Israel (Hashiloni-Dolev and Shkedi, 2007). As such, genetics, reproduction, and disease at times enact a kind of 'somatic responsibility' (Rose, 2007) rooted in the individual. But this nexus also generates what Prainsack and Siegal (2006) call 'genetic couplehood,' wherein genetic identity supersedes the individual and instead focuses on the couple in relationship to their community.

Genetics: Legal Aspects

Shawn HE Harmon, University of Edinburgh, Edinburgh, United Kingdom

Abstract

The legal challenges of emerging genetic practices are numerous and fundamental. Not only has genetics destabilized concepts of personhood, community, health, and disease, but also it has complicated the regulation of many fields, throwing into question settled concepts and mechanisms. This article highlights a range of live legal issues and then focuses on issues found in four settings: newly emerging research models, commercial practices associated with genetics, food security, and the practice of law. It concludes by suggesting that we are little closer to determining the appropriate role and form of law in relation to genetics than we were a decade ago.

Introduction

Genetics has prompted dramatic shifts in diverse fields such as human reproduction, medical diagnostics, epidemiology, toxicology, agriculture, environmental rehabilitation, and more. In doing so, it has thrown into question traditional definitions of personhood, individuality, community, health, and disease, and traditional assessments of risks (to individual or public health or the environment) (Grodsky, 2005). With respect to disease, for example, genetics, which relies on the idea of 'biomarkers' (i.e., it approaches the study of the genome by looking at the placement and order of gene sequences), has suggested the existence of continuums from healthy to diseased, and from exposure to disease, which have become important to reproductive, developmental, neurological, immunological, and other health impairments, particularly those relating to cancer and environmental exposures (Perera, 1996; DeCaprio, 1997; Marchant, 2003).

The rapid evolution of genetics has also, importantly, given rise to ethico-legal concerns, some of them new, many of them well-rehearsed. From a legal perspective, some questions that have been much debated, though hardly settled, include the following:

- What is the most appropriate legal consequence of characterizing the genome as the common heritage of humanity? How do we reconcile the fact that an individual's genetic information is both intimately private and shared across family and (sometimes) community? For more on these questions, see Knoppers (2005) and Ossorio (2007).
- What are the appropriate limits of science? Where do we set the boundaries of acceptable research given our ambitions, our rudimentary understanding of biological mechanisms, and our relatively powerful technical capabilities (to clone animals and human tissue or to alter genetic germlines to both plants and animals)? For more on these questions, see Jasanoff (1987), Clayton (2003), and Wainwright et al. (2006).
- How do we balance the need (and desire) to facilitate science and technological innovation with the need to protect individual rights, cherished social values, and traditional cultural norms? What is the appropriate role of the scientific regulatory regime? How does it optimally interact with other regimes? How do we avoid regulatory overburden and complexity? For more on these questions, see House of Lords (2009), Academy of Medical Sciences (2011).
- How do we integrate new genetic understandings and the more precise data we are generating into existing science and risk-based assessments, whether environmental, public health, or other? How do we cope with the detail and complexity that are being generated? What does our greater understanding of the susceptibility of population subgroups mean for standard setting? For more on these questions, see Grodsky (2005) and Caulfield et al. (2012). In the US context, see American Lung Association v EPA (1998).
- How and to what extent should new genetic tools that assess predisposition (and the treatment options to which they give rise, which are often not yet genetic, e.g., abortion) be integrated into public health systems? How effective are existing genetic counseling services? How can the often expensive technologies to which genetics research gives rise be made more accessible around the world as part of our moral and human rights–based responsibilities to share in scientific knowledge and preserve the health of all humans? How practical and realistic are ambitions for personalized medicine, or even stratified medicine? In short, how do we cope with genetic knowledge and technologies at the clinical level? For more on these questions, see Acheson et al. (2005), Drahos (2007), and Mittra and Tait (2012).

As should be clear from this nonexhaustive list, the range of concerns with which the law is interested is broad, but all of them implicate to varying degrees notions of

- risk (to individual health, community identity, and environmental well-being);
- choice (of patients, health care providers, and consumers);
- values (dignity, autonomy, sanctity, solidarity, equality, and democracy); and
- rights (to tissue, data, patents, privacy, and decisional freedom).

Generally, in each category, the law would prefer certainty, which is a fundamental principle of the law (Alexy, 2004). However, while genetics does offer a previously unimagined precision when it comes to understanding the structure of biology (if not the diagnosis and treatment of conditions and

complex diseases), it has proven rather more destabilizing when it comes to the law. The result has been that how we permit genetic knowledge and innovations to be deployed remains open and contested, with most commentators encouraging caution, engagement, attention to context, and preservation of existing rights.

Obviously, the full range of legal issues could not possibly be addressed in a single article. This article, therefore, focuses on four issues that directly and deeply implicate the law, and that might be considered consequent of the relative maturation of genetics – a maturation that has seen genetic science taken up in applied fields despite, it must be admitted, the persistent and acknowledged uncertainty surrounding much of our knowledge. This article examines sociolegal concerns arising from the use or interaction of genetics with (1) new scientific methods, (2) the commercialization of science, (3) food production and security, and (4) the operation of law.

New Scientific Methods and Approaches

To begin with the science itself, genetics has given rise to new research models. Population biobanking and bioinformatics-reliant genome-wide association studies are just two examples of how the practice of science has transformed as a result of advances in genetics (House of Lords, 2009). Biobanks are collections of tissue and data for future use by diverse researchers, some of whom will be extraterritorial; they are complex research undertakings embedded in complex research networks (Kaye et al., 2012), and they raise critical and novel questions as to the following (Harmon, 2008):

- Appropriate recruitment and consent procedures
- Appropriate stewardship responsibilities and standards of conduct
- Appropriate long-term maintenance procedures for the resource
- Appropriate access criteria to the resource
- Appropriate monitoring of use and governance of the resource
- Appropriate benefits to participants, including feedback of incidental findings

Exhibiting structural diversity, purposive uncertainty, and temporal longevity, they are, by their nature, exercises in the unknown, and that makes them particularly challenging for law (Laurie, 2011). As such, key questions include the following:

- How do we regulate these new scientific models so that they are sustainable?
- How and where does law fit into that regulatory regime?

While some jurisdictions have opted for a legislative approach (e.g., Estonia, Latvia, Norway, Sweden, and Spain), many have not. The UK Biobank, which is subject to the Human Tissue Act 2004, has adopted an "ethics+" approach (Laurie, 2011). This means that legal standards, found in a range of instruments, are supplemented by an evolving ethical and oversight framework that goes beyond the law and contains a public participation component.

Of course, biobanking is not the only novel scientific method (or socioscientific undertaking) that has arisen. Assisted by innovations in high-speed gene-profiling technologies (e.g., miniaturized semiconductor chips, laser and robotics engineering, and DNA microarrays) that allow for comprehensive analysis of gene expression at unprecedented speeds and scales, a variety of new approaches to the study of genetics are being explored. These so-called postgenome approaches, such as systems biology, gene ecology, and epigenetics, are more organismic and relational in nature (Wynn, 2005; Powell and Dupré, 2009). They shift the analysis from intrinsic elements like functional outcomes of genetic sequences and their mutations to the interactions between systems; they have thus been described as the biology of the in between (Van de Vujver, 2009). Such new approaches trigger new legal questions and controversies, and reignite old ones.

For example, epigenetics adopts a more complex and contextual approach to gene expression than traditional genetics (Waddington, 1942). Appreciating that the body is embedded in different environmental circumstances, epigenetics suggests that these circumstances can be inscribed on gene expression (i.e., not on the structure of the sequence but on how the gene is expressed physiologically) (Kuzawa and Sweet, 2009; Barrès et al., 2012). It holds that heritable characteristics can arise from marks on the genome, or the scars of experience that influence gene expression. The temporalities considered to be relevant are

1. evolutionary (across generations);
2. developmental (early origins of adult disease);
3. life course (environmental exposure to conditions); and
4. real time (day-to-day).

This epigenetic model blurs the boundary between the biological and the social in which it exists. In doing so, it reemphasizes and intensifies the complexity and uncertainty that traditional genetics has already introduced (Niewöhner, 2011). A major scientific concern is that this complexity could unravel much of what we 'know' from past scientific methods or frames about biology and nature. This, in turn, could undermine the legal rules and presumptions that rely on scientific understandings. For example, as awareness of the role of epigenetics in normal and abnormal cell development grows, so has the realization of the potential importance that epigenetic disruptions (such as toxicity and environmental regulatory priorities) can have for human well-being, now and into the future (Dolinoy et al., 2007; Jirtle and Skinner, 2007). Shifts in accepted knowledge will affect a range of legislated standards, including those around air and water purity, toxins exposure, food quality, and more; swathes of legislative regimes may have to be revisited with respect to the thresholds of exposure and standards of conduct they permit (In the United States, implicated legislation includes the Clean Air Act, 42 USC §§ 7401, et seq.; the Clean Water Act, 33 USC §§ 1251, et seq.; the Toxic Substances Control Act, 15 USC §§ 2601, et seq.; the Comprehensive Environmental Response, Compensation and Liability Act, 42 USC §§ 9601, et seq., the Resource Conservation and Recovery Act, 42 USC §§ 6901, et seq.; the Safe Drinking Water Act, 42 USC §§300f, et seq.; the Federal Insecticide, Fungicide and Rodenticide Act, 77 USC §§ 136(a), et seq.; and the Occupational Health and Safety Act, 29 USC §§

651–78 (2000). In addition, FDA authorizations of food products and medicines under the Federal Food, Drug and Cosmetic Act, 21 USC § 301 et seq.; are implicated, particularly requirements for efficacy of drugs.).

Additionally, epigenetics will continue the trend of generating masses of information about an individual's likelihood to develop health problems in the future and transmit them to children. This means that more sensitive health information will be generated and will, by necessity, be shared across projects and health systems; it means that information disclosures will become more common and more diffusive, particularly as individuals claim rights of access to others' health information that they see as relevant to them (Laurie, 2002). Because of the social stigma that attaches to some conditions (and to ill health more generally), concerns about privacy, confidentiality, and the sufficiency of existing protections abound (Rothstein, 1997; Andorno, 2004). This will be a particular challenge for data curators charged with information protection and access duties under data protection legislation (In Europe, data management is governed by EU Directive on Data Protection 1995/46/EC, which has been transposed into Member State law. In the United Kingdom, the relevant statute is the Data Protection Act 1998.).

Finally, epigenetics raises the specter that we might (consciously or unconsciously) naturalize individual or community social situations through the creation of a biological frame for those situations (Busby and Martin, 2006; Niewöhner, 2011). In examining the reframing of food as a form of metabolic environmental exposure, Landecker argues that nutritional epigenetics, in addition to destabilizing our understanding of food, contributes to 'a molecular politics of eating' that implicates notions of personal and social responsibility for the future health of individuals and populations and the governmental stewardship of food (Landecker, 2011: 168). In other words, if we construct and institutionalize science to reflect or bolster social conditions, then we risk perpetuating those conditions and neglecting the (difficult) political, social, ethical, and legal solutions that we should be pursuing as part of our moral or legal responsibilities (such as making healthy food accessible, providing quality education, etc.).

These concerns do not exhaust the legal implications of epigenetics, but rather demonstrate that concerns over genetic determinism, reductionism, exceptionalism (which asserts that the occurrence of specific conditions or diseases is directly caused by specific genes without more, and that we are little more than the sum of our genes, which, from birth, describe our fate), and the medicalization of human conditions (which describes how we have turned all manner of social conditions into medical conditions to be remedied) remain very much alive despite our growing understanding of, and aversion to, them (Mittra, 2007). Therefore, we have to remain vigilant to issues such as characterization, issues that were highlighted by genetics and become more pronounced with further developments.

Commercialization of Genetic and Cellular Inventions

Genetic science is closely allied with commercial interests; indeed, the Human Genome Project was in a race against a commercial competitor to map the human genome. Given the relative infancy of the science and the relatively modest range of practical health care products to which it has so far given rise, commercial activity has concentrated on compiling intellectual property portfolios relating to research tools and techniques and to diagnostics. That is, research entities have focused on obtaining patents on genes, gene sequences, processes for culturing cells, and so on. This, of course, raises questions about the propriety of patenting genes and the research or diagnostic products derived from living human material (not to mention questions about how genetic and cellular products fit into existing regulatory frameworks applicable to the market authorization of medical devices and medicinal therapies).

According to the dominant liberal dogma, patents encourage and promote innovation, competition, and economic growth, so the expansion of patenting is good not only for the economy but also for science (European Patent Office [EPO], 2012). While patenting is governed by domestic laws, the field is very much harmonized internationally. European signatories must conform to the European Patent Convention (1973), and members of the World Trade Organization (WTO; 157 members by October 2012) must conform to the TRIPS Agreement (1994). Generally, patents afford patentees a nationally bounded, exclusive, 20-year monopoly to exploit an invention in that jurisdiction in exchange for public disclosure of the invention. Many inventions are patented in multiple countries. To be patentable, an invention must meet certain criteria, namely

- novelty;
- nonobviousness (contains an inventive step that takes it beyond the state of the art); and
- utility (has some industrial application).

In addition, the disclosure of the invention in the patent application must be such that an individual conversant in the field could replicate it. Importantly, a mere discovery of nature, or of a naturally occurring substance or phenomenon, is not patentable, nor, at least in Europe, is anything that contravenes morality or *ordre public*.

Diamond v Chakrabarty (1980) is attributed with extending patentability to living products and, therefore, to genes. In that case, the US Supreme Court held that "anything under the sun made by man" is patentable. The TRIPS Agreement (1994) dispelled any lingering doubts as to whether patents involving living material were patentable when it stipulated, in Article 27, that patents shall be available for any inventions in all fields of technology. A similar approach was adopted in the EU's Biotechnology Patenting Directive 1998/44/EC. Since these clarifications, genetic science has been the subject of frantic commercial activity, with thousands of gene patents having been issued around the world. By 2000, there were some 4200 gene patents worldwide (Jensen and Murray, 2005), and, by 2005, the United States had issued some 40 000 DNA-related patents (Torrence, 2010).

Given the significant wealth at stake (e.g., the global biotech industry is estimated as having an annual revenue of US$228.6 billion; IBISWorld, 2012), it is not surprising that numerous patents have been challenged as stakeholders try to determine how the patenting criteria will operate in the genetics field. In

the United Kingdom, Genentech Inc.'s Patent (1989) and Kirin-Amgen Inc. v Hoechst Marion Roussel Ltd. (2004) confirmed that isolated gene sequences are patentable inventions so long as the inventor has demonstrated how it can be usefully employed. In Biogen v Madeva (1997), the House of Lords held that a product produced by different processes from an existing product is not novel, and that overbroad claims can be fatal. In Harvard College v Canada (2002), the Canadian Supreme Court offered guidance on the sufficiency of disclosure in patent claims. In the United States, Amgen Inc. v Chagai (1991) and Fiers v Revel (1993) confirmed gene patentability and held that claims must not be too broad or generic; the gene must be chemically isolated and specific claims as to application must be made.

Recently, however, the general position of patentability has been thrown into some doubt by Association for Molecular Pathology v USPTO (2011), wherein the US Federal Circuit Court held that isolation of a gene does not change it from being a mere discovery of a natural phenomenon. The Court of Appeal reversed this decision, but in the much-criticized case of Mayo Collaborative Services. v. Prometheus Laboratories (2012), the US Supreme Court offered new guidance on the natural phenomenon doctrine that could limit gene patentability, and it remanded the case back to the Federal Court. These cases could, arguably, be seen as a tentative retreat from cases such as In re Deuel (1995) and Eli Lilly v Human Genome Sciences (2011), US and UK cases respectively, which were characterized as victories for the biotechnology industry over patent law requirements (Ducour, 1996).

Aside from these technical conflicts between competitors, gene patents have been challenged on a more fundamental basis. Arguments against so-called life patents include the following:

- They are contrary to the idea of the genome as the common heritage of humanity (i.e., as part of the commons that should be open to all to use; it is a global public good).
- Genes are natural products, so these patents are mere discoveries despite the fact that they have been purified and isolated by human ingenuity (a process that is no longer novel).
- Gene patents confer overly broad protections for largely unproven applications over things (DNA sequences) that have little utility on their own.
- Gene patents unduly instrumentalize humans, particularly vulnerable early-stage humans, and are therefore contrary to morality.

Opposition grounded on these arguments, which are value based, has led to legal challenges, particularly in Europe.

First, EU Member States challenged the EU Biotech Directive on both technical and substantive grounds; neither Netherlands v European Parliament and Council (2001) nor Commission of the European Communities v Italy (2005) was successful, but both elucidated important elements of European law (Plomer, 2012). Next, using a patenting procedure unique to Europe, stakeholders challenged the patenting of inventions the base material for which originated in human embryos and their destruction. Two EPO cases, EDINBURGH (2002) and WARF (2008), offered, for the first time, a more expansive view of the exclusions to patentability, giving patenting antagonists hope. More recently, in Brüstle v Greenpeace (2011), the European Court of Justice held that inventions relying on embryonic stem cells derived from methods destructive to the embryo are not patentable because they are contrary to public morality. In doing so, and contrary to common scientific views, it extended the definition of embryo to that collection of cells that exists from conception, thereby limiting the possibility of obtaining patents in the embryonic stem cell research setting. These value-based cases could be seen as victories for dignity- and rights-based advocates who view any interference with the building blocks of life with fear or skepticism. The bottom line is that the field is still very much contested and evolving.

Genetically Modified Food

Nutritional and environmental awareness are growing social phenomena, and food security is a growing legal concern globally as arable land diminishes and populations grow. The development of genetically modified organisms (GMOs) and genetically modified foods (GMFs) thus is a focus for a range of sociolegal issues.

GMOs generally trigger concerns over environmental risks, and legal disputes relating thereto have been fought. Very basically, some stakeholders are concerned about GMO contamination of non-GMO crops, fields, and habitat. Though few cases have been prosecuted, many incidents of contamination have been reported, and it is generally agreed that fines for infringements are derisory. As in the pharmaceutical setting, the conduct of large corporations is often viewed suspiciously, a disposition encouraged by their introduction of characteristics such as sterility into traditionally sustainable products that are needed by farmers often operating on very fine margins.

For example, Monsanto developed so-called terminator seeds, seeds with genes that render second-generation seeds sterile, thereby tying farmers to the corporate supplier. A seminal case is Monsanto Canada Inc. v Schmeiser (2004), in which the fields of a canola farmer were infected with his neighbor's genetically modified canola produced and patented by Monsanto. Upon discovery, he was sued by Monsanto for patent infringement. The Supreme Court of Canada found that Schmeiser was indeed using seeds that he had neither purchased nor licensed. Nonetheless, it held that he had made no excessive profit and so need not pay damages to Monsanto or the company's (hefty) legal costs. *Monsanto* highlights not only the weakened position of the farmer in this new agricultural order, a matter over which the law ought to be deeply concerned, but also the potential consequences of the superior survivability of GMOs, which gives them resilient, weed-like characteristics that could endanger the survivability of other plants.

These factors, together with the more fundamental concerns that stakeholders have with organisms that have been human altered at the genetic level, have led to calls for strong regulation of GMOs and GMFs. The US approach, which relies on the Department of Agriculture (USDA), the Food and Drug Administration (FDA), and the Environmental Protection Agency (EPA), can be described as minimalist, and is generally

supported by international institutions such as the WTO and the Food and Agricultural Organization (FAO). By contrast, and more in keeping with many developing countries, the European approach is more precautionary and interventionist. It has adopted instruments addressing the risk assessment of GMOs, the release of GMOs, and the import and sale of GMOs and GMFs (and GM animals) (See EU Directive on Genetically Modified Micro-Organisms 90/219/EC, EU Directive on Deliberate Release of GMOs 2001/18/EC, Regulation (EC) No. 1829/2003 on GMFs and Feed, and Regulation (EC) 1946/2003 on Transboundary Movements of GMOs.). This regulation is informed by the idea of advanced informed consent as articulated in the Cartagena Protocol on Biosafety (2000) and the precautionary principle (which asserts that, where there are threats of serious damage beyond a *de minimus* range from a given activity, lack of full scientific knowledge about, or proof of, those threats must not be used as a reason to avoid or postpone cost-effective measures to minimize or avoid them; Rio Declaration, 1992; Clarke, 2005). As one might imagine, as with other areas of genetics, regulatory burden and regulation-driven cost are issues for operators in the field.

Shifting from cash crops to dinner tables, strong public resistance to GMFs has arisen. This resistance is fueled by all or some of the following factors (Wagner et al., 1998):

- Revulsion toward GMFs (leading to unhelpful caricatures such as Frankenfoods)
- Inaccurate understandings about GMOs
- Legitimate concerns around issues such as novel allergenic proteins and zoonosis (the transfer of animal viruses and diseases to humans)

British and European responses to GMFs have been particularly vociferous (Gaskell et al., 1999), even implicating the criminal law. In the United Kingdom, for example, in DPP v Bayer (2003), an individual who believed that a crop of GM maize was dangerous to people and to nearby fields was convicted with aggravated trespass for entering onto land and disrupting the crop.

Because many people wish to avoid GMFs, the content and quality of food labels have become important legal issues. Unfortunately, the Codex Alimentarius, which ought to offer leadership in this regard, has failed to do so. Again, the United States takes a hands-off approach, and a 2004 report fell short of calling for GM labeling but did recommend greater scrutiny of GMFs, including improved postmarket surveillance (National Research Council, 2004). In Europe, GMFs and food labeling are governed by EU Regulation (EC) No. 258/97 on Novel Foods, and Regulation (EC) No. 1830/2003 on Traceability and Labelling of GMOs. Basically, they require labels to declare GMF status if a foodstuff contains more than a stipulated percentage of GM material.

The above concerns have given rise to the idea of "food forensics"; the practice of applying science to determine the extent and nature of genetic modification in any given food substance (Heller, 2006). This will become more important as labeling requirements tighten and GMFs become more common. Indeed, as foods begin to exhibit medicinal qualities (like the GM rice that was claimed to inhibit hay fever), their classification as food is called into question altogether. Such products will require food and pharmaceutical regulatory institutions to jointly determine which regulatory pathway is more appropriate. This will necessitate a good deal more joined-upness than currently exists.

All told, GMFs represent a particularly controversial example of how genetics has transformed a series of sectors that are fundamental to human existence. It has changed how food, which we all need, is manipulated, discussed, and protested. Food is now considered and contested on a molecular level; its molecular structure or genetic constitution is highlighted by innovations in science because it is partly human-made, and consumers wonder about the effect of those (artificially introduced) genes once digested (Landecker, 2011). Thus, in addition to giving rise to legal issues of environmental safety, biodiversity, and the ownership of agricultural production, GMFs give rise to the more social phenomenon of thinking of, visualizing, and controlling food as molecules that interact with our molecules (Landecker, 2011).

Genetics and the Operation of Law

The previous sections have focused on how genetics has given rise to new practices (research, commercial, and agricultural) to which the law must respond. This section focuses on how genetics can and is (1) eroding fundamental rights, (2) challenging long-held legal doctrines, and (3) being used by the law (or in legal proceedings and peoples' interactions with the state). Essentially, as will be shown, genetics is forcing us to revisit how we ensure that rights are enjoyed and how we conceptualize important legal concepts, and it is contributing to the reshaping of the practice of law and how legal conflicts are decided.

With respect to the first issue, the enjoyment of fundamental rights, concerns abound that genetic science might dilute, wither, or destroy existing rights and interests. Genetics has unquestionably given rise to new forms of categorizing people (according to genetic susceptibility), and this has, in turn, unquestionably given rise to new forms of discrimination: so-called genetic discrimination, which is differential treatment of asymptomatic individuals or their relatives on the basis of their presumed susceptibility to known diseases or conditions as extrapolated from genetic differences assumed or demonstrated by predictive genetic testing. While our tendency toward genetic determinism has been much lamented (Greely, 2001; Curley and Caperna, 2003), there is ample evidence that genetic discrimination has been widely experienced, particularly in insurance and employment (Mittra, 2007; Taylor et al., 2008).

Drawing on the values of dignity and autonomy, and on equality, privacy, and other rights, stakeholders have challenged the idea that genetic susceptibility is an appropriate ground on which to limit access to benefits (Rothstein and Anderlik, 2001; Mayor, 2003) and lawmakers have responded. With respect to insurance, they have either adopted specific statutes or agreed moratoria on the use of genetic information by insurers (Morrison, 2005; Lemmons, 2010). With respect to work, legislation has also been adopted protecting employment rights; in the United States, note the Genetic Information Non-Discrimination Act of 2008. At the same time, questions have been raised as to whether genetic susceptibility might

constitute a disability entitling individuals to make certain claims to benefits. In the United States, this issue was highlighted by Save Our Summers v Washington Department of Ecology (1999) without being settled.

Given the international nature of science, it is unsurprising (and indeed quite helpful) that leading international organizations have offered some guidance on how genetics might interact with rights. Indeed, many general and specific international legal instruments aimed at articulating norms and setting standards for the new genomic age have been fashioned, many of them intended to serve as models for national legislators drafting their own laws. Examples include UNESCO's Universal Declaration on Human Rights and the Human Genome (1997), International Declaration on Human Genetic Data (2003), and Universal Declaration on Human Rights and Bioethics (2005); the Council of Europe's Convention on Biomedicine and Human Rights (1997) and its related protocols; and instruments offered by entities such as the World Health Organization and the Organization for Economic Cooperation and Development.

With respect to the second issue, alteration of long-standing legal concepts, the quintessential example is property. It has long been the position in law that property cannot be held in the undivided human body, whether living or dead. Universal antislavery laws negate the former, and a range of instruments have resulted in the position that corpses can be possessed only for purposes of disposal. Precedents to this effect stretch back centuries: Haynes Case (1614), R v Lynn (1788), and Williams v Williams (1882). More recently, in R v Bentham (2005), the House of Lords held that a person does not 'possess' his body or any part of it, though excised body parts can be owned by the originator or a third party if skill has been applied (such as dissection or preservation) that gives the body part new properties. In this regard, Doodeward v Spence (1908), Moore v Regents of the University of California (1990), and R v Kelly (1998), Australian, American, and English cases respectively, are pertinent. With the rise of genetics and the fantastic economic value that potentially rests in cells and DNA, individuals are now claiming ownership in their bodies and bodily products. Lawyers, however, are unsure whether to characterize DNA as tangible property, intellectual property, or something else for the purpose of assigning control and entitlements to benefit, a fact that has been described as worrying (Foster, 2003). And as with many of the above issues, positions are shifting, a fact demonstrated by Yearworth and Others v North Bristol NHS Trust (2009), a UK Court of Appeal case that extended property rights in semen to its originators. For more on this, see Harmon (2010).

With respect to the third issue, reliance on new genetic knowledge and tools is expanding dramatically, making the jobs of lawyers, judges, and civil servants (e.g., border agents and police officers) more complicated and difficult insofar as they must be aware of how genetics can be used across a field and within any given case. Once that threshold is crossed, there are issues around actually obtaining samples for examinations; in many jurisdictions, individuals are entitled to rights of physical inviolability and to not be a witness against themselves. Once access is addressed, the reception of this evidence into legal proceedings, whether civil or criminal, must be managed, and judicial (and many administrative) proceedings have very specific methods for receiving technical evidence and accepting something as fact. Curiously, while much genetic science deals only with probabilities, it has been largely readily accepted by courts and the public (Cadlish, 2010). Indeed, scientific evidence presented by experts is sometimes viewed as more compelling than other, more traditional forms of evidence (such as witness observations), and popular portrayals of the use of DNA and science-derived evidence bolster this view.

Table 1 Applications of genetics in different legal fields

Areas of law	*Application*
Criminal	Matching tissue or forensic samples
Humanitarian	Determining time of death
	Determining or confirming identity
Immigration	Determining paternity and fidelity
Human rights	Determining (familial) relationship
Family	
Wills and estates	
Tort (privacy)	
Tort (negligence; medical)	Assessing causation for claimed injuries
Trade	Tracing products and materials
Environmental	Testing risks and risk management strategies
Sports	Testing for performance enhancements

Table 1 lists just some of the legal fields, both public and private, that are increasingly relying on genetic science to perform their functions effectively.

The difficulties are exemplified by a very brief look at just one field: Actors in the environmental field are increasingly confronted with new science-based challenges to regulatory decisions and decision-making processes, and new understandings and complexities will have to be taken into account when making or justifying policy and judicial decisions. Genetics is thus forcing a revisitation (and sometimes an alteration) of (1) decisional criteria, (2) permitted standards of conduct, and (3) entitlements to rights and/or benefits because it is constantly redefining and refining what we consider to be risks, and much of our environmental (as well as our medical and public health) law and policy relies on the idea of risk. Note the American Thoracic Society's recognition that evaluations of adverse health effects might shift its evidentiary reliance from clinical symptoms to biomarkers (American Thoracic Society, 2000), and note Chlorine Chemistry Council v EPA (2000), wherein the US District Court required the EPA to abandon its traditional assumptions and defaults for assessing carcinogenic properties (of chloroform) in favor of "the best available peer-reviewed science." Grodsky (2005: 240) has argued,

> The genomic revolution is likely to invigorate ongoing debates about the relative merits of "science-based"and "science-blind" regulatory approaches. Importantly, this fundamental debate may help reveal the structural elements of new approaches that could be considered in the future.

The author goes on to argue, quite rightly, that, because we do not fully understand the nature of future challenges or the solutions that science may provide, regulatory approaches that

encourage the generation, evaluation, and incorporation of new information are most useful. (So, bad news if you are a technophobe.)

Conclusions

This article has demonstrated that advances in genetic knowledge, and new approaches to studying genes, diseases, and the human condition, have given rise to difficult legal issues with respect to

- regulating the conduct of science and its commercialization;
- making decisions and setting standards in fields that rely on science (and scientifically grounded notions of risk);
- protecting and revising established rights (such as privacy and property rights); and
- prosecuting and defending claims, both civil and criminal, through the law.

Fundamentally, we remain unsure what role we want the law to play (or think it can play) in the development of genetic technologies, a matter identified as critical over a decade ago (Black, 1998). More practically, despite the now decades-long use of genetics in some legal or policy fields, we are still struggling with issues such as technical transparency, standardization of lab practices (particularly in the criminal law context), and challenges to professional and scientific competence.

This article is a revision of the previous edition article by N.L. Pedersen, volume 9, pp. 6116–6118, © 2001, Elsevier Ltd.

Abstract

In this article, the findings from behavioral genetic studies of personality are summarized, including twin and adoption studies estimating heritability as well as molecular genetic studies of candidate genes and genome wide association studies. Studies of biological markers and other personality correlates are also reviewed, with suggestions for future directions in genetic studies of personality. An overview of personality theories and assessment instruments of personality is also provided.

With roots reaching back as far as ancient Greece and the four Hippocratic temperamental humors, the study of personality and its hereditary basis has a long history. 'Personality' refers to a set of tendencies, attitudes, emotions, and behavioral patterns that characterize an individual. Conceptualized as a series of traits rather than any single defining characteristic, personality encompasses one's temperament character, attitudes, and worldviews. Personality research suggests that certain traits and tendencies are enduring patterns, and not merely state dependent or fleeting. Consistent with this finding, we intuitively recognize that people's behaviors are largely stable and not arbitrary. Most widely used personality instruments in research adopt this 'trait approach,' although others using a typological approach are also used in clinical and other applied settings.

One consistent finding in personality research is that almost all traits show moderate genetic influence, or *heritability*. Genetic analysis has been applied in abundance to dimensional traits. The findings from behavioral genetic studies of personality are summarized in this article, starting with twin and adoption studies estimating heritability as well as molecular genetic studies of candidate genes and genome wide association studies (GWAS). Studies of biological markers and other personality correlates are also reviewed, followed by future directions in genetic studies of personality. An overview of personality theories and assessment instruments of personality is first provided.

What Is Personality?

Before considering its genetic and environmental basis, it is worth reviewing the major theories and definitions of personality. Although 'personality' is a common lay term, there has historically been a lack of consensus within the scientific community as to its definition and constitution. Modern personality theories consider such different areas as (1) understanding individual traits and the relationships amongst them; (2) investigating personality dimensions related to psychopathology; and (3) the use of typological approaches to understanding personality.

Personality Theories: Traits vs Typologies

No single theory of personality is accepted by all psychologists. Several theories posit different traits or dimensions of personality, although several major traits are often found across these models. The most commonly studied of these is the Five Factor Model (FFM), commonly referred to as the 'Big Five' (McCrae and Costa, 1987), which is comprised of extraversion (engagement with the external world), neuroticism (proneness to negative feelings and experiences), openness to experience (novelty and curiosity), conscientiousness (organization and efficiency), and agreeableness (friendliness and compassion). The FFM has also been found to reflect two higher order factors (Digman, 1997), the first of which (α) is defined by agreeableness, conscientiousness and neuroticism, which is thought to be similar to Adler's 'social interest.' The second factor (β) is comprised of extraversion and openness to experience and may reflect such concepts as Maslow's 'self-actualization.' The FFM has much in common with an earlier theory of personality that specified three traits, including two found in the Big Five (extraversion, and neuroticism), and a third (psychoticism – reflecting aggression and proneness to unusual thinking) (Eysenck and Eysenck, 1975). Another major personality theory is a seven-factor model proposed by Cloninger et al. (1994), which consists of four temperaments (harm avoidance, novelty seeking, reward dependence, and persistence), and three character traits (self-directedness, self-transcendence, and cooperativeness). The first two temperaments are similar to neuroticism and extraversion, respectively. Of these theories, the FFM has by far received the most attention from behavioral genetic research, in part due to its reliability and reproducibility cross-culturally. Among these instruments, it is also the most brief (as few as 40 items) and easy to administer (self-report questionnaire).

In addition to dimensional personality models (i.e., trait approaches that yield quantitative variation), there exist several notable models that use a qualitative or typological approach. The most well recognized of these is the Myers-Briggs Type Indicator (Myers, 1962), which is based on Jungian theory and focuses on four dichotomies (extraversion–introversion; intuitive–sensing; thinking–feeling; judging–perceiving) and yields 16 possible personality types reflecting all possible combinations of the four dichotomies. Another typological approach with considerable attention is the Enneagram, which examines nine interconnected personality types based on core motivations and fears. One challenge that emerges for these typological personality instruments is that traditional quantitative genetic methods (e.g., correlations among relatives) cannot be easily applied to their resulting categorical variables.

Personality across Development

In children, researchers typically refer to temperament characteristics rather than personality. One theory suggested three temperamental *types*: easy, difficult, and slow to warm up (Chess and Thomas, 1987, 1990), as well as nine temperament *traits*: activity level, distractibility, intensity, regularity, sensory threshold, approach/withdrawal, adaptability, persistence, and mood (Thomas and Chess, 1977). These have been found to predict personality traits at the age of 18, as well as interpersonal relationships, social support, employment status, and psychiatric disorders at the age of 21 (Caspi, 2000).

Although personality is often considered a stable set of traits, research has found that changes in personality occur throughout development, even in adulthood and into old age, with the most changes during adulthood occurring between the ages of 20 and 40 (Roberts and Mroczek, 2008). Personality tends to change across age toward increase in self-confidence, warmth, self-control, social dominance, and emotional stability. Consistent with the idea that personality can change across development are findings from a recent meta-analysis of 92 studies across the age span of 10–101 years, showing mean level changes over the course of life, with significant changes in 75% of traits in middle age and beyond (ages 40–60 and 60+; Roberts and Mroczek, 2008).

Personality Assessment

Personality is typically measured through self-report instruments. Individual differences in response patterns to questions about personal behavior and attitudes remain stable across even decades – that is, the rank ordering of individuals on personality traits remains similar across time, in spite of the fluctuations as described above (Costa and Mccrae, 1992). The instruments most often studied in genetic research of personality are those that assess the FFM, such as the 240-item NEO-PI Revised (Costa and Mccrae, 1992). The 100-item Eysenck Personality Questionnaire (EPQ; Eysenck and Eysenck, 1975) measures the traits of psychoticism, extraversion and neuroticism. The Multidimensional Personality Questionnaire (MPQ), consisting of 276 questions, measures 11 primary traits (well-being, social potency, achievement, social closeness, stress reaction, alienation, aggression, control, harm avoidance, traditionalism, and absorption) into three higher order factors that are potentially comparable to openness, neuroticism, and conscientiousness, namely positive emotionality, negative emotionality, and constraint, respectively (Tellegen, 1982). The 240-item Temparament and Character Inventory (TCI) measures personality through Cloninger's seven-factor model (Cloninger, 1987). Brief versions of these instruments are also available and widely used, for example, a 40-item FFM (Thompson, 2008) and a 48-item EPQ (Eysenck et al., 1985).

In addition to those inventories that examine facets of personality, there exist several prominent measures often used in clinical psychology research and that are concerned with pathological aspects of personality. The most common of these is the Minnesota multiphasic personality inventory (MMPI-2; Butcher, 1989), a 567-item self-report measure aimed at discerning tendencies toward deviance and psychopathology in addition to some normative personality features. The MMPI-2 has several validity scales built into it, which are designed to identify whether individuals are attempting to portray themselves more negatively (e.g., faking mental illness) or more positively (e.g., feigning social desirability). Similar mental health and personality assessments exist, such as the personality assessment inventory (Morey and Lowmaster, 1999) or the California personality inventory (CPI; Gough, 1957).

Genetics of Personality: Twin and Adoption Studies

Behavioral genetic studies often utilize twin or adoption designs and are aimed at answering questions of 'nature and nurture' by comparing covariation of variables between individuals who are known to share specific proportions of genes. For example, comparing correlations for a given trait between 'identical' monozygotic (MZ) twins (who share 100% of their genes) and 'fraternal' or non-identical dizygotic twins (who share 50% of their genes on average) can help discern how much genetic influence exists for that trait. These studies often constitute the first step in establishing heritability (h^2) of an observable trait (i.e., the proportion of observable variance in a trait that can be explained by genetic differences among people), and may serve as rationale for further molecular genetic investigation in order to identify specific genes involved in personality. The earliest and most consistent finding from behavior genetics studies is that all personality traits have some heritable component (Loehlin and Nichols, 1976). Another notable finding from most studies discussed below is that environmental influence on personality stems from nonshared environment, meaning environment that is unique to each individual and not shared by twins. That is, individual experiences appear to be most important to shaping personality, rather than the shared environment among twins and other family members.

A large portion of behavior genetics research conducted on personality has utilized the FFM. Typically, all five factors emerge as primarily influenced by genetics and nonshared environment, with little if any effect of shared environment. Heritability estimates are 40–50% for facets of the FFM (Loehlin, 1992), with remaining variance being explained by nonshared environment. This is consistent with broad estimates of heritability between 30 and 50% on all personality facets, including those from other instruments such as the EPQ, CPI, and Junior Temperament and Character Inventory (JTCI) (Plomin et al., 2008; Jang et al., 1998). Some studies have examined the cross-cultural structure of influences on the FFM, and have found that the structure, both genetic and environmental influences and correlations amongst them, remains stable across cultures from North America, Asia, and Europe (Yamagata et al., 2006). Personality stability appears to be influenced largely by stable genetic influences, whereas change over time (across the age span of adolescence to late middle age) is due largely to changes in environment (Kandler et al., 2010). At least one twin study analyzed the α (neuroticism, conscientiousness, agreeableness) and β (openness, extraversion) traits and found that genetic influences were best represented as exerting their effects through latent common variables of α and β (Jang et al., 2006).

Individual differences in other personality traits can be explained by similar proportions of genetic and nonshared

environment influences. Sensation-seeking, harm avoidance, reward dependence, and persistence are each influenced by genetics (h^2 = 35–60%) (Heiman et al., 2012; Zuckerman, 1994), as are Cloninger's seven personality factors (h^2 = 30–50%) (Gillespie et al., 2003). When Cloninger's and Eysenck's models of personality were jointly examined, six separate genetic and environmental sources of influences were found, suggesting the two sets of traits may not be entirely redundant with one another, but rather that each represents an incomplete description of personality with different underlying genetic etiologies (Heath et al., 1994). Akin to the g-factor of general cognitive ability or intelligence, a general factor of personality (GFP) has been proposed from factor analyses of the FFM that provide an alternative to α and β findings (Musek, 2007; Rushton et al., 2008). This GFP is comprised of desirable personality traits such as low neuroticism, extraversion, and conscientiousness, and has been found to be influenced by genetics (h^2 = 46–53%) (Veselka et al., 2009).

For childhood temperament specifically, heritable influences in five dimensions that somewhat overlap but are not entirely redundant with adult FFM traits have been examined. These temperament traits were activity level, anger–frustration, behavioral inhibition–fear, effortful control, and positive effect, each of which showed similar proportions of genetic influence to the adult FFM traits, with heritability estimates ranging between 38 and 58% (Gagne et al., 2009).

In spite of their popular interest, there has been a notable lack of behavioral genetic research on categorical measures of personality (i.e., typological approaches). There exist no reliable estimates of the heritability of typological personality assessments such as the Myers–Briggs or the Enneagram, regardless of their growing popularity and use outside of research settings. However, when the Myers–Briggs categories were examined as continuous variables, thinking–feeling and introversion–extraversion were found to be about 60% heritable and sensing–intuition and judgment–perception were found to be about 40% heritable (Bouchard and Hur, 1998).

Genetic Influences on Correlates of Personality

In addition to studying genetic influences on personality directly, it is also possible to investigate heritable influences on *behavioral correlates of personality*, including traits involved in both mate selection and the success (or failure) of romantic relationships. While no genetic influence has emerged for individual differences in mate selection itself (Lykken and Tellegen, 1993) or romantic style in love (Waller and Shaver, 1994), propensity to divorce was found to be 52% heritable in both men and women (McGue and Lykken, 1992). Moreover, 30–42% of the genetic influence on risk of divorce overlapped with genetic influences on the personality factors of positive emotionality, negative emotionality, and constraint of the MPQ (Jockin et al., 1996).

What about the abnormal or pathological aspects of personality? Some psychologists conceptualize personality disorders (PDs) to be pathological manifestations of normative traits. The 10 personality disorders outlined in the *Diagnostic and Statistical Manual* (DSM-IV) are theorized to cluster into three categories: A (odd/eccentric), B (dramatic), and C (anxious). Multivariate genetic analysis of traits corresponding to these 10 PDs found influence of three genetic and three environmental factors. The first genetic factor loaded onto all 10 PDs, while the second loaded only onto borderline and antisocial traits (both within the 'dramatic' B cluster), and the third loaded onto schizoid and avoidant traits (both within the 'odd/eccentric' A cluster). The environmental factors loaded onto the three defined DSM-IV clusters almost perfectly with the exception of obsessive-compulsive personality disorder, which was influenced only by unique environmental influences. Several PDs are influenced by unique genetic or environmental influences not shared with other PDs. In all, heritability estimates ranged from 20 (schizotypal) to 40% (antisocial), falling in line with personality heritability estimates for normative traits (Kendler and Aggen, 2008). Further evidence for similar ranges of heritability in pathological personality dimensions come from genetic studies of the MMPI or MMPI-2, which find h^2 = 25–57% in the clinical scales (Viken and Rose, 2007; Gizer et al., 2010). Moderate genetic overlap emerged amongst the scales, with positive genetic correlations among them, except for mania with depression and social introversion, and hypochondriasis with social introversion, which showed negative genetic correlations (Viken and Rose, 2007).

Another question is whether major psychological disorders might be extreme manifestations of normal varying personality traits. Genetically informative studies have attempted to address this by investigating the genetic overlap between major personality traits of extraversion and neuroticism with categories of externalizing and internalizing disorders, respectively. Indeed, internalizing disorders including anxiety, depression, and phobias appear to have some genetic overlap with the personality trait neuroticism (Hettema et al., 2008). Extraversion, on the other hand, does not appear to overlap genetically with externalizing disorders such as antisocial personality disorder and substance abuse (Khan et al., 2005). Instead, the externalizing disorders appear to be more related to disinhibition and (lack of) constraint (Krueger et al., 1996).

Biological Substrates of Personality

Certain endocrine and neurobiological measures have been associated with personality features. The study of the heritability of these measures has provided additional clues about the underlying physiological mechanisms of personality. For example, asymmetry of activation in the prefrontal cortex has been associated with positive emotionality and an approach tendency, which are related to low neuroticism and openness (Davidson and Fox, 1982; Coan and Allen, 2004). The heritability of frontal asymmetry is somewhat low in children (h^2 = 0–21%; Gao et al., 2009), and moderate in adults (h^2 = 27–37%; Anokhin et al., 2006; Smit et al., 2007), although there is little or no research on the genetic overlap of this asymmetry with personality.

Another biological substrate of personality is cortisol, a stress hormone related to anxiety, chronic stress, and irritability. Naturally occurring cortisol levels in blood, saliva, and urine were found to be heritable (h^2 = 60%; Bartels et al., 2003). In addition, cortisol reactivity to stress is also a relevant measure of one's natural response patterns, and this appears to be 56–97% heritable (Federenko et al., 2004).

Molecular Genetics of Personality

Although there have been many examinations of specific genes and their involvement in personality outcomes, the results have been marked by inconsistency. One common form of molecular genetic research is association studies, which involve candidate genes, or specific alleles with different variants that are differently related to measurable traits. Several candidate genes are frequently studied in personality and psychopathology research, typically using genes that are involved in neurotransmitter systems. Cloninger's theory of personality posits that dopamine is the dominant neurotransmitter system involved in novelty seeking, serotonin in harm avoidance, and norepinephrine in reward dependence (Cloninger, 1993). These neurotransmitters are related to the candidate genes most often explored.

The first of these neurotransmitter systems is dopamine, involved in mood, reward response, learning, attention, arousal, and other important functions. Dopamine receptor D4 (DRD4) was first found to have a long variant associated novelty seeking (Cloninger, 1993), but several subsequent studies failed to replicate this finding or found the contribution was negligible (Ebstein et al., 1997; Kluger et al., 2002). The dopamine receptor D2 (DRD2) gene was also found to be associated with novelty seeking (Berman et al., 2002; Light et al., 2007).

Another frequently examined candidate gene is the serotonin transporter gene (5HTTLPR), the short form of which has been associated with neuroticism (Lesch et al., 1996). However, this too has failed to replicate (Flory et al., 1998) A recent meta-analysis found the following associations significant: (1) approach motivation and the DRD4 c > t polymorphism, and DRD3 A1/A2 polymorphism; (2) avoidance traits and the 5HTTLPR polymorphism, DRD4 c > t polymorphism, DRD2 A1/A2 polymorphism and DRD3 A1/A2 polymorphism; (3) aggression traits and 5HTTLPR polymorphism, and DRD3 A1/A2 polymorphism (Munafò et al., 2003). However, due to some failures to replicate even within the studies in this meta-analysis, there remains skepticism in the field about any one of these genes' direct contributions to personality.

Some genes found to associate with personality have involvement with several neurotransmitter systems. For example, transcription factor AP-2β has binding sites that are involved with regulating several genes related to dopamine (DβH, DAT1, DRD1a), as well as serotonin (5HTTLPR, 5HT2a) and acetyl choline (ChAT), and is active largely during development. The short allele variant of this gene has been associated with higher anxiety and muscular tension in both men and women (Damberg et al., 2000). Another transcription factor, brain-derived neurotropic factor has a single nucleotide polymorphism (SNP), producing either a valine or a methionine amino acid in the outcome protein. The methionine variant of this SNP has been associated with lower trait neuroticism (Sen et al., 2003).

Overall, although candidate gene studies represent an optimistic avenue for genetic research into personality, study results so far have been contradictory and effect sizes small. One proposed problem with these studies is that they tend to be underpowered because the involvement of any particular single-locus genotype on a complex trait is very minimal (Martin et al., 1997). Several newer genetic research methods have similarly produced little insight into genetic origins of personality. For example, GWAS use large sample sizes (as high as $N > 10\ 000$) and approximately 500 000 to 2 million loci to search for SNP association to trait variation or disease vulnerability. These studies have not found significant associations of any one gene with any personality trait (van den Oord et al., 2008; Terracciano et al., 2010). Notably, these GWAS studies did not find significant associations with some of the candidate genes most often examined, such as DRD4 or 5HTTLPR.

The majority of linkage studies – which use within-family designs to test for chromosomal regions contributing to variance in personality traits – have concentrated on the trait neuroticism, and one consistent replication suggests involvement of chromosome 12 (Fullerton et al., 2003; Kuo et al., 2007; Gillespie et al., 2008). Additionally, individual differences in emotional liability (which is akin to neuroticism) have been associated with a broad region on chromosome 8p (Cloninger et al., 1998; Fullerton et al., 2003; Dina et al., 2005). Overall, the inconsistency of results across GWAS, linkage and association studies suggests that personality is immensely complex and likely shaped by intricate interactions among a large number of genes, as well as by environmental influences on those genes.

Conclusions and Future Directions

Personality traits have consistently emerged as moderately heritable, with genetic factors accounting for about 30–50% of the observed variance in each trait, regardless of the measuring instrument or theoretical approach. The environmental influences on personality have consistently emerged as being of the nonshared variety, such that the unique experiences of each individual rather than shared experiences among family members appears to shape the development of behavioral and emotional response patterns.

Among the many molecular genetic studies of personality, the vast majority has focused on a small number of well-studied candidate genes, which account for only small percentages of personality variance at best. There are likely thousands of genes that comprise the complex organization structure of personality and that have yet to be researched. As new sequencing, synthetic biology, and bioinformatics methods emerge for identifying genetic regions involved in behavior, our ability to extract more reliable information should increase considerably. In addition, it is important to consider the potential involvement of gene by environment interactions (GxE) in the development of personality. GxE refers to the interplay between genes and the environments that may affect them, and some evidence already exists to suggest that specific environment does activate genetic disposition. For example, harsh home environments have been found to interact with certain alleles of DRD2, 5HTTLPR, or the monoamine oxidase A gene in producing more antisocial behavior (Caspi et al., 2002; Retz et al., 2008). A GxE association between genetics and hostile environment has also been found in novelty seeking for DRD4 (Keltikangas-Järvinen et al., 2004) and DRD2

(Keltikangas-Järvinen et al., 2009). Arguments have been made to suggest that effects of any one genetic variant may be too minimal to be detected without the consideration of GxE (Bronfenbrenner and Ceci, 1994; Munafò and Flint, 2011).

Another field of genetic research that is gaining increasing attention is *epigenetics*, which studies molecular changes to DNA and gene expression due to environmental conditions. This represents direct research into GxE mechanisms, and could potentially explain how behavioral differences in MZ twins come about. Epigenetic changes to the DNA do not affect sequence but affect the shape of the molecule and its folding patterns. One commonly studied epigenetic mechanism is methylation – a process by which methyl groups become attached to DNA nucleotides. A strand's 'methylome' can affect not only the way in which it folds, but also its attractiveness for transcription, both of which can have profound effects on genetic expression. Evidence for epigenetic effects in personality have already emerged in MZ twins with different levels of risk-taking behavior (Kaminsky et al., 2009). As bioinformatics methods advance and become capable of more efficient calculation and simulation, more information regarding molecular genetics will become available.

Lastly, but perhaps most importantly, the challenge that faces geneticists seeking answers about personality is a lack of consensus about what personality actually is. Different theories of personality may overlap, but are not completely redundant. There are questions about whether personality should be measured within a person's own trait organization or in comparison to others (Cervone, 2005). It has also been suggested that in addition to self-report or behavior, endophenotypes (e.g., biological markers) and behavioral assessments need to be included in definitions of personality (Jang and Yamagata, 2009). Others have suggested altogether that personality is not nearly as stable as is assumed, but is rather situational, with patterns to the situational variance (Mischel and Shoda, 2008). Until personality concepts and their assessment are refined to a point of agreement among personality theorists, questions will remain about whether genetic studies are accessing the correct constructs.

Genetics: The New Genetics

Karen-Sue Taussig, University of Minnesota, Minneapolis, MN, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

This article explores what is new about contemporary genetic research. The article examines the everyday work of genetic research and clinical practices in and beyond the laboratory; understandings of human biological variation, including race and ancestry; and the intersections of science, citizenship, and subjectivity. In examining these aspects of contemporary scientific knowledge production, the article demonstrates the deeply social nature of every aspect of contemporary genomics.

The concept of a new genetics emerged in the mid-twentieth century as a term to refer to research newly informed by James Watson and Francis Crick's (1953) discovery and description of the helical structure of the deoxyribonucleic acid (DNA) found in every living cell (Ekberg, 2007). The new genetics can perhaps best be understood not simply as a subject of biological inquiry but also as a cultural object, simultaneously producing and produced by cultural meaning and practice. Its many dimensions operate in diverse social domains and geographical locales. With its etymological roots in the idea of generation, genetics has virtually always been a future-oriented phenomenon that simultaneously invokes the past. Here we see ideas about expectations (e.g., Brown and Michael, 2003), promise (e.g., Fortun, 2008; Tutton, 2011), hope (e.g., Brown, 2003), hype (Rajan, 2007), and potential (e.g., Taussig et al., 2013) at work, as genome researchers articulate genomics as the royal road to improving the human condition. The shifts in thinking and practice associated with this new knowledge occur simultaneously with institutional and cultural changes through which the new genetics is taught, learned, and experienced.

The idea of *new* raises the question of precisely what is new and what is old in this area of contemporary research. After discussing the idea of when genetics was new, this article highlights three overlapping themes associated with the new genetics broadly conceived, exploring both the emergent and historical antecedents. The first theme involves the everyday work of scientific research and clinical practices in and beyond laboratory and medical settings. The second theme focuses on issues related to human biological variation, including those having to do with race and ancestry. The third theme deals with issues at the intersections of science, citizenship, and subjectivity. Intersecting all of these themes are issues about the body, commerce, governance, and the nature of life. Further, examination of these themes illuminates not simply the 'social impact' of new knowledge and technologies. Rather, it illustrates the deeply social nature of every aspect of the new genetics, demonstrating that the social is not after the fact of scientific or technological innovation, but that the knowledge and practices associated with the new genetics are never outside of the grip of culture.

When Genetics Was New

We might say that genetics was first new in 1865 when Gregor Mendel presented his paper, *Versuche Über Pflanzenhybriden* (*Experiments on Plant Hybridization*), elaborating the heritability of traits in peas at the meetings of the Natural History Society of Brünn in Moravia, or in 1866 when he published the paper in the Society's journal. The paper was well received but essentially ignored, its significance only apparent when it was rediscovered virtually simultaneously by Hugo de Vries (1900) and Carl Correns (1900) more than three decades later. The history of genetics from this founding through its transformation into eugenics – a term coined by Francis Galton in 1883 to refer to the idea of improving the human stock through encouraging and discouraging specific kinds of human matings – and the explosion of eugenics into a worldwide movement promoted by cutting edge scientific theories of the time in the early decades of the twentieth century, is rather well rehearsed (e.g., Kevles, 1985; Lombardo, 2008; Paul, 1995; Stepan, 1991; Stoller, 1997).

The systematic adoption of eugenic theories in Nazi racial and health policies ultimately laid bare their logical ends (Ekberg, 2007; Kevles, 1985; Paul, 1995; Proctor, 1990), thereby producing the desire, indeed the need, to create genetics anew. Recognizing the potential horrors embedded in the eugenic theories that had come to dominate their discipline, in the post-World War II era geneticists sought to distance themselves from these theories. They did so by working to distinguish the science itself from what were perceived as the social uses to which that science might be put and by separating human and nonhuman genetics (Keller in Kevles and Hood, 1992). In particular, when attending to human genetics, they focused on basic processes of physiology, acknowledging the complexities of human behavior and leaving it outside the purview of this new genetics. This genetics focused on understanding processes of heredity in order to improve diagnosis of and develop treatments for heritable diseases (Keller in Kevles and Hood, 1992; Kevles in Kevles and Hood, 1992).

Watson and Crick's (1953) publication of their discovery of the structure of DNA offered a particularly robust opportunity for shifting genetics onto new terrain that focused on understanding inheritance through genetic structure. This watershed moment, along with Joe-Hin Tjio and Albert Levan's 1956 publication convincingly articulating the number of chromosomes in a human cell into which DNA is spooled, both validated the value of focusing on this basic science and energized such efforts (Kevles in Kevles and Hood, 1992). Watson and Crick's findings supported the flourishing of this new genetics as molecular biology, including the development of

recombinant DNA (rDNA). At least by 1969, scientists began imagining this genetics as providing tools for transforming human health, articulating possibilities of animating bodies, and extending life in new ways (Sinsheimer, 1969) through intervention in life at the molecular level.

The interplay between molecular theories and practices, on the one hand, and this imaginary of healthier and longer human lives, on the other, provided the impetus and foundation for the establishment of the Human Genome Project (HGP) in the late 1980s with an initial commitment of $3 billion in funding from the U.S. government. The goal of the project was to map a complete human genome (the full complement of DNA in a single organism) that would provide a foundation for improving human health and well-being. A first draft of the human genome was announced in June 2000 and the project was declared completed in 2003.

With the establishment of the HGP, the idea of *new* became increasingly tied to a genetics associated with the genome project and the knowledge and technologies the project was producing. *The New Genetics* has since come to refer not just to the HGP, but also to all of the allied genetics (e.g., epigenetics), genomics (e.g., genomics itself, pharmacogenomics), -omics (e.g., proteomics, microbiomics, metabolomics), and novel techniques (transgenics, cloning, stem cell science) that at least in part have been built, in both the academy and the private sector, on the foundation of knowledge and techniques developed through the HGP. These endeavors have also supported the development of new medical technologies (e.g., assisted reproduction; pre- and postnatal genetic screening and testing), of new or expanding medical disciplines (e.g., genetic counseling, medical genetics, bioethics), and of direct-to-consumer commercial ventures selling genetic information (e.g., 23andMe). While framed by the idea that knowledge of the human genome could lead to dramatic medical breakthroughs, the technologies developed through the project have been adopted in other, highly diverse, domains as well – in, for example, genetic ancestry research, proving or disproving paternity or other forms of kinship, practices associated with identifying human remains after natural disasters or from mass graves, agricultural practices associated with crops and animal husbandry, and policing/criminology where DNA evidence and identification have been added to the forensic tool kit. Taken together, these efforts involve enormous financial, institutional, and cultural investments including the establishment of new academic disciplines and departments in new buildings, the development of biotechnology as a multibillion dollar sector of the economy, and the emergence of new ways of understanding humanness and human relations. As such, they are part of global commercial enterprises that have been identified under the rubric of biocapital (Helmreich, 2008). These phenomena have received significant attention from scholars interested in understanding this complex social field.

Scientific Research and Clinical Practices

In its contemporary form, we see research and clinical practices associated with the new genetics organized around an active imaginary that is simultaneously about the nature of life broadly conceived and the potential of human capacities and longevity. In contemporary scientific research and clinical practices associated with the new genetics, we see the reimagining of life, efforts to transform human capacity including the capacity for health, and emergent forms of scientific governance.

Reimagining Life

The new genetics has emerged in the context of knowledge and practices that have allowed biological materials to exist and reproduce in diverse ways outside of the bodies in which they previously resided (e.g., the reproduction of cells through tissue culture – the growth of cells derived from living tissue in an artificial medium – or the production of persons through *in vitro* fertilization). Often moving genetic material or cells across species, such practices challenge understandings of life constituted in specific (species) form and, thereby, reshape how we are able to think about life. Here I focus on three key insights into how these endeavors challenge assumptions about life. First, examining the development of tissue culture, Hannah Landecker argues that this phenomenon "changed the placticity and temporality of living things [which] thus may be harnessed to human intention" and, in so doing, "changes what it is to be biological" (Landecker, 2007: 1 and 235). The ability to grow cells into tissue and, thus, sustain life outside of the body in which those cells originated provides the technological grounds for many of the assisted reproductive technologies and related applications associated with the new genetics.

This shift in what it is to be biological was perhaps made most publicly visible in the 1997 announcement of the production of Dolly, a sheep, described as a clone, produced through the laboratory technique known as somatic cell nuclear transfer (Wilmut et al., 1997). In her analysis of Dolly, Sarah Franklin offers a second insight into life in the context of the new genetics. What was revolutionary about the cloning of Dolly, Franklin tells us, was not the cloning itself. Prior to Dolly, scientists virtually unanimously believed that the cloning of a large mammal was impossible. The cloning of Dolly did not simply prove that it was possible to clone a sheep but, rather, it did away with the notion of the biologically impossible itself (Franklin, 2001; see also Rheinberger, 1995). In other words, the advent of practices associated with the new genetics such as tissue culture and cloning have opened up new horizons for creative thinking about life in terms of what cells and the genetic materials they contain can do and can be made to do.

These horizons involve the third insight into life in the context of the new genetics – that is, the ability to redistribute life. In this potential for redistribution, as Stefan Helmreich elaborates, we find both 'life forms' and 'forms of life' in flux. For Helmreich, life forms refer to organisms, species, types of creatures, or ecological relations among creatures, while forms of life point to the "social, symbolic, and pragmatic ways of thinking and acting that organize human communities" and through which "action becomes meaningful" (Helmreich, 2009: 6). Here Helmreich is in conversation with the work of biologist Lynn Margolis and the science writer Dorian Sagan who theorize life not in terms of concrete organisms, but in terms of an open thermodynamic system "always emerging into an assortment of bodied manifestations" (Helmreich,

2009: 279). It is in relation to the dynamics of life illuminated here that we can best understand the ongoing emergence of the new genetics since the advent of the HGP.

Transforming Human Capacities

One of the most persistent characteristics of the HGP has been the promises made by those who have supported and worked on it that the new knowledge the project would develop would lead to a molecular medical tool kit that would facilitate dramatic improvements in human health. In thinking about the effects of the HGP, it is useful to distinguish between the project itself – the mapping of 'the human genome,' which can be understood as a project of structural genomics – that is an effort to understand the basic structure of a human genome – and the ongoing activities that have increasingly moved to center stage since the June 2000 announcement of a first rough draft of the genome, which can be understood as a project of functional genomics – that is, the aim of developing greater understanding of gene function through understanding the complex pathways from genetic sequence to the expression of particular traits, especially those associated with complex human capacities and diseases.

The first domain in which this new knowledge has had significant effects involves assisted reproductive technologies. Here we see efforts focused on the prevention of genetic conditions (e.g., cystic fibrosis, Tay–Sachs disease, Huntington's chorea, sickle cell disease) in the explosion of techniques through which genetic material is separated from the bodies in which it originates for amniocentesis and prenatal genetic testing; preimplantation diagnosis involving *in vitro* fertilization; and postnatal genetic testing. With the new genetics, researchers increasingly identified chromosome differences and genetic mutations associated with particular genetic anomalies. With the technical ability to isolate fetal cells from amniotic fluid, culture them, and evaluate them for such anomalies and, in the context of legal abortion, amniocentesis as a means of evaluating the genetic qualities of a fetus has become a routine aspect of reproduction in those places where such technologies are socially available and culturally meaningful (Rapp, 1999). With these practices and techniques in place, as new mutations are identified, it is a relatively simple matter to develop a prenatal diagnostic kit through which any newly recognized mutation might be identified in a particular fetus (see, for example, Taussig et al., 2003).

Although researchers certainly realized there would be a 'therapeutic lag' between the mapping of the genome and the development of useful clinical interventions, the promises made by HGP researchers were not simply about prevention, but about treatment. The goal was and remains a revolution in medicine through which a molecular medical tool kit will be mobilized to intervene in genetic conditions. Importantly, genome project proponents always emphasized that they were not just talking about rare single-gene conditions such as cystic fibrosis for which they imagined the establishment of gene therapy as a useful therapeutic intervention, but about widespread common conditions such as cancer, diabetes, heart disease because, as they argued, every embodied condition has a genetic component related to risk for and susceptibility to disease. For these more common conditions, they imagined not just gene therapy, but the tailoring of medical and pharmacological treatment to the specifics of an individual patient's genome (Kevles and Hood, 1992).

While efforts are still underway to develop gene therapy, to date it has repeatedly failed and, in fact, appears to have killed more people than it has helped. In this light, researchers have turned to other avenues, including genome-wide association studies, stem cell research, epigenetics, and synthetic biology, each heralded in turn as the big thing that would dramatically improve human health. All of this work has led to remarkable insights into life and to a handful of significant clinical applications, but none of it has yet led to the hoped for revolution in medicine. This is a space that is suffused with ideas about realizing particular human futures and efforts to shape the social relations perceived as necessary for realizing those futures.

Governance

The new genetics associated with the HGP emerged in tandem with the expression of concerns to address issues of governance in scientific research and in related clinical and forensic practices (Bunton and Peterson, 2005; Gottweis, 2002, 2005; Hindmarsh and Prainsack, 2010). A precursor to these efforts can be seen in the 1975 Asilomar Conference on Recombinant DNA. The conference brought together key researchers to discuss the risks to lab and public safety posed by new research involving rDNA technologies (which involve combining the DNA from distinct organisms) that had been made possible through techniques developed by Stanley Cohen and Herbert Boyer (Cohen et al., 1973). The conference established voluntary guidelines for using rDNA in research, including a moratorium on certain kinds of experiments, in order to ensure the safety of those working in such labs and of the broader public. Asilomar offers an example of scientific self-governance in which issues of safety in and beyond the lab were of central concern to scientists themselves (Hindmarsh and Gottweis, 2005; Weiner, 2000).

In contrast, in the face of concerns about the broad social implications of the new genetics and worry that such concerns might inhibit research, the HGP established the ethical, legal, and social implications (ELSI) of the HGP program. In so doing, the project devoted a percentage of HGP funds to the ELSI program for the study of, among other things, governance issues associated with human subject protections (e.g., privacy, informed consent, individual autonomy, the regulation of data) and intellectual property. Rather than following the voluntary self-governance model of Asilomar, these efforts were explicitly intended to identify issues of concern and shape formal government regulations associated with the research, knowledge, and clinical practices involved in the new genetics (see e.g., Meslin et al., 1997).

The establishment of ELSI led to a major infusion of money – $125 million in the first 13 years of the program – into scholarship in this domain, supporting, in particular, a flourishing of bioethics. Indeed, in the early days of the HGP, bioethicist Arthur Caplan described the project as "a full employment act for bioethicists," while others refer to the development of an 'ELSI industry' that has emerged internationally in relation to the new genetics (Hoeyer and

Tutton, 2005). From its inception, the HGP's ELSI program was enmeshed in controversy over its engagement – or lack thereof – with broader issues of power and distributive justice. The very framing of 'ethical, legal, and social,' these critiques suggest, elides the political, the economic and the moral. In exploring the political implications of contemporary governance of the new genetics, Klaus Hoeyer and Richard Tutton suggest that ethics is used here to as a "kind of assurance that potential or actual ethical problems have been identified, attended to and resolved." They argue that the result of this use of ethics is that "no matter how ambitious or controversial, biomedical research is then able to progress" (Hoeyer and Tutton, 2005: 386). These critiques suggest that tensions between concepts of regulation and enablement are inherent in the governance of the new genetics and its emergent biotechnological practices, raising questions about science subjectivity, and citizenship to which I will return after attending to issues of human biological variation also engendered by new genetic knowledge.

Race, Ancestry, and Human Biological Variation

Questions about the nature of human variation have been central to the new genetics. Here we see interest in using the tools produced by the new genetics to elucidate an evolutionary story about the history of the human family, including the relatedness of all species (e.g., Helmreich, 2009; Marks, 1995, 2002). At the same time, the idea that humans are profoundly similar at the molecular level is always in tension with the recognition that it is the differences that lead to disease and embodied affliction. The June 2000 announcement of the completion of a first draft of the human genome celebrated the unity of the species, with President Clinton stating that at the level of the genome, "the only race is the human race." Yet, those working on the project almost immediately intensified work on understanding the differences that might aid in illuminating ancestry, on the one hand, and disease processes, on the other. An early effort in this direction involved the Human Genome Diversity Project of the 1990s (Reardon, 2004 and cross reference). More recently, such efforts are visible in the 2002 establishment of the International HapMap Project that aimed to describe patterns of human variation in order to facilitate research on human disease and pharmaceutical responses. This project explicitly sought to understand human variation by gathering genetic samples initially from four populations with continental origins in Africa, Asia, and Europe. In developing the project, researchers were careful to characterize the samples they collected in locally specific terms. For example, samples from 'the Yoruba people of Ibadan, Nigeria.' Nevertheless, as the cell lines were taken up in subsequent research, they often were described simply as 'African.' Here we see how genetic material can become racialized in practices associated with the new genetics, a process Jonathan Kahn (2012: 34–36) describes as "racial recursion."

In such approaches to understanding human variation, we find ideas and assumptions related to folk theories about the relations between and within species, including those associated with race and racial difference (e.g., Abu El-Haj, 2007; Bolnick et al., 2007; Fujimura et al., 2008; Hartigan, 2008; Koenig et al., 2008; Wade et al., 2014; Wailoo et al., 2012). Here we see the tools of the new genetics utilized to engage a racialized human history and its contemporary manifestations in research and clinical practice. Given that much contemporary research associated with the new genetics focuses on the implications of human variation at the molecular level, of particular concern in this domain is the persistent ways that race gets used in medical practice as a proxy for genetic difference (Duster, 2007; Fullwiley, 2007; Kahn, 2012; Root, 2003) and that, at the same time, in forensic DNA profiling, genetic material is used to signify race and race is used to organize genetic data (Duster, 2006; Hindmarsh and Prainsack, 2010; Kahn, 2009; Krimsky and Sloan, 2011). Thus, while the completion of a first draft of the human genome provoked statements about the unity of the species, the new genetics also has been marked by a peculiar reemergence of race in genetic research and in clinical and forensic practices.

Science, Citizenship, and Subjectivity

In their essay on biological citizenship, Nikolas Rose and Carlos Novas make the point that many citizenship projects have been "framed in biological terms; in terms of race, blood lines, stock intelligence, and so forth" (2005: 440). Pointing to the significance of biology and citizenship in his book about the politics of inclusion in medical research, Steven Epstein (2007: 318 n. 13) points to a growing list of citizenship concepts related to science and understandings of biology – e.g. scientific citizens, biological citizenship (noting two distinct approaches to this concept), genetic citizenship, and therapeutic citizenship. The contemporary emergence of these concepts highlights the complex ways that new scientific knowledge implicates understandings of both citizenship and subjectivity.

The biological dimensions of citizenship associated with the new genetics can be found in at least two arenas of work in this area. The first involves the social conditions of enablement that facilitate access to the material means of contemporary knowledge production. The second can be seen in what, with Deborah Heath and Rayna Rapp, I have elsewhere described as genetic citizenship.

Social Conditions of Enablement

It has long been understood that knowledge production in the life sciences depends upon the "right tools for the job" (Clarke and Fujimura, 1992). While genetic research has now long relied on access to genetic material, what is new in contemporary research in this area is that the right tools for the production of new genetic knowledge requires access to vast quantities of data. The demand for this data is part of the move, described above, from the structural genomics of the HGP to the functional genomics of contemporary genetic knowledge production. In the structural project aimed at developing a map of a human genome, access to virtually any human genetic material would suffice. Functional genomics, which seeks to understand the complex pathways from the presence of a particular genetic sequence to the specifics of how it is

expressed in any one individual, requires access to large quantities of genetic material attached to medical records and family histories in order to help illuminate how any particular sequence is expressed in a unique individual in a particular family at a specific time. These material demands of contemporary knowledge production associated with the new genetics have engendered a range of efforts to establish the social relations perceived as necessary for researchers to gain access to such materials. Emblematic of these efforts are calls to make participation in medical research an obligation of citizenship (Schaefer et al., 2009) and attempts to establish genetic biobanks in diverse locales, including both national banks – e.g. Iceland, the United Kingdom, Japan, Italy, Sweden, and Taiwan – and banks associated with specific medical centers – e.g. the Mayo Clinic, Vanderbilt University Medical Center, and the recently established Million Veterans Project.

In some locales, efforts to encourage participation in such biobanking have led to a range of projects that aim to invite diverse citizens to engage in genetic thinking and practice. That is, they attempt to educate people about the new genetics in part to encourage them to participate in genetic research or to contribute to a genetic biobank. In the United States, for example, the National Institutes of Health (NIH) recently contracted with the Johns Hopkins University's Genetic & Public Policy Center to conduct focus groups and a set of national town hall meetings to engage a wide array of U.S. citizens in a conversation about whether and under what conditions they would be willing to participate in a national NIH-based genetic biobank. In the context of the Hapmap project discussed above, significant attention was paid to engaging members of target communities in conversations about the effort prior to collecting the genetic samples that would be made into cell lines for the project's biobank.

At the same time, lack of knowledge about genetics among physicians is widely seen as inhibiting the translation of new genetic knowledge into clinical practice. Repeated studies have shown that, as a group, physicians have little sense of when to order genetic tests or how to interpret them (e.g., Gaff et al., 2007; Hayflick et al., 1998; Hunter et al., 1998). Significant efforts are now underway to incorporate the new genetics more systematically into medical education. Such education is also viewed as a crucial component of establishing the social relations necessary for the flourishing of the new genetics, because physicians are often the ones who will refer patients to participate in genomic research or draw their blood for inclusion in a biobank.

Genetic Citizenship

The concept of genetic citizenship (Heath et al., 2004; see also Taussig et al., 2003) points to classic issues of citizenship having to do with the politics of inclusion and exclusion. Deborah Heath, Rayna Rapp, and I explore the reconfiguration of activism in the context of citizenship claims made by lay advocacy organizations in relation to the new genetics.

Knowledge and technologies associated with the new genetics persistently raise questions about belonging, as people are faced with reproductive choices about genetic testing, and about what makes an acceptable member of their family and of the human species that such testing provokes. National policies that shape the public (national health insurance) and private (corporate insurance) logics behind the coverage of such medical procedures also come in to play here, since the calculus of covering prenatal genetic testing involves balancing that cost with the cost of covering the care of a fragile child and it always occurs in the context of the politics of access to abortion.

In the United States and elsewhere, this push to perfectibility has emerged virtually simultaneously with the disability rights movement and the claims for dignity and inclusion of which lay advocacy groups supporting those with genetic conditions are actively involved. It is, for example, in this context that the lay advocacy organization for people of short stature produced a t-shirt emblazoned with the words 'Dwarf: Endangered Species' upon the publication of the discovery of the FGFR3 gene responsible for achondroplasia, the most common form or dwarfism in humans. While many people who have this dwarfing condition welcome this finding because it allows them to undergo prenatal testing to discover whether they are carrying a fetus with the nearly always fatal (at birth) condition of double dominance (two copies of the already dominant gene for achondroplasia), the t-shirt points to their recognition that this knowledge may be used for eugenic purposes by those in the wider population (Taussig et al., 2003).

In developing the concept of genetic citizenship, Heath, Rapp, and I point to how the experiences of those at the vanguard of genetic decision-making – whether researchers, clinicians, individuals or families bearing distinctive genetic conditions, or members of the lay public – connect "discussions of rights, recognitions, and responsibilities to intimate, fundamental concerns about heritable identities, differential embodiment, and an *ethics of care*" (Heath et al., 2004: 157 italics in the original). Genetic citizenship points both to "the political economy of state funding and regulation and the unruly aspirations of scientists, health advocates, health-care service providers, and families, sometimes struggling against the market, sometimes seeking, whether ardently or ambivalently, to join it in an effort to imagine other possible futures" (p. 165). Those involved in lay advocacy organizations associated with genetic conditions undertake crucial work in care, research, and policy. They often fund significant research on the condition with which they are concerned; facilitate essential access to the genetic material, family histories, and medical records so crucial to understanding the epidemiology of a particular condition and to discovery of the genetic sequence to which it is connected; intervene with legislators to ensure policy supporting that research; and even work to shape commercial aspects of that research through claiming a share in resulting intellectual property. In the activism of those involved in lay advocacy organizations, we see the complex ways the new genetics implicates citizenship and subjectivity as it opens up new or newly configured domains for political engagement and demands for rights and inclusion.

EDITOR IN CHIEF BIOGRAPHY

James D. Wright received his bachelor's degree in philosophy from Purdue University in 1969, a master's degree in sociology from the University of Wisconsin in 1970, and his PhD in sociology from Wisconsin in 1973. His first academic appointment was at the University of Massachusetts, Amherst, where he was promoted to Associate Professor in 1976 and to Full Professor in 1979. Most of his 15 years at Massachusetts were spent as Director, Associate Director, or Director of Research in the Social and Demographic Institute.

Wright left Massachusetts for Tulane University in New Orleans in 1988 where he served as the Charles and Leo Favrot Professor of Human Relations in Tulane's Department of Sociology. He also enjoyed a courtesy appointment in the Tulane School of Public Health, Department of Biostatistics and Epidemiology. He left Tulane in 2001 to become the Provost's Distinguished Research Professor of Sociology at the University of Central Florida. In 2003, he was named as the Director of the University's Institute for Social and Behavioral Sciences and in 2013, was designated as a UCF Pegasus Professor, the University's highest faculty honor.

Wright was the Editor in Chief of the scholarly journal *Social Science Research* from 1978 until 2014. His previous editing experience also includes a 20-year stint as editor of the Aldine de Gruyter book series *Social Institutions and Social Change*, two editions of the *Handbook of Survey Research* (Academic Press, 1983; Emerald Publishing, 2010), and service on the editorial boards of numerous journals. He is the author of 21 books and scholarly monographs on topics ranging from homelessness to research methods to NASCAR, and he has published more than 300 journal articles, book chapters, reviews, essays, and polemics. Wright lives with his wife Christine Stewart and their multiple dogs and cats in Winter Springs, Florida, where in his spare time he likes to cook fancy meals for large crowds.

PREFACE TO THE FIRST EDITION

Large and ambitious works such as the present Encyclopedia depend on countless instances of input, cooperation, and contextual support. Therefore, the editors in chief would like to express their gratitude to several institutions and individuals. Our most general thanks go to our respective home institutions, the Center for Advanced Study in the Behavioral Sciences, Stanford, and the Max Planck Institute for Human Development, Berlin. We are certain that without the effective infrastructures of these institutions and the rich collegial networks and intellectual climate they provide, implementing this Encyclopedia in such a short amount of time would not have been possible. In this context, we also need to mention that due to the administrative budgets provided to the editors in chief by the publisher, the financial strains on our home institutions were minimal. Such a situation may be a rarity in the modern world of scientific publishing where publishers often press scholars and institutions into taking on larger and larger shares of the publication enterprise.

Aside from the more than 4000 authors, our deepest thanks goes to the editors of the 39 sections, to whom we delegated many decisions at various stages, who were primarily responsible for developing the lists of articles and authors, and who stood as the main gatekeepers of scientific quality for the entries in their sections. As a group, the section editors displayed remarkable energy, intelligence, and tolerance for the inevitable frustrations of tending large numbers of authors over a long period of time. Because of the brevity of the acknowledgment of the main editorial coproducers here, we alert the reader to the list published as part of the front matter and the description of their extensive work we offer in the Introduction. We would also like to mention that one of our highly esteemed section editors, Franz Weinert, died unexpectedly during the last phases of his editorial work. For people who had the pleasure of knowing Franz Weinert, it comes as no surprise that he completed his editorial duties without ever complaining about the difficult health conditions he was facing. He was a gentleman and a distinguished scholar.

The International Advisors also gave wise counsel on several designated occasions, and a number of these scholars represented on the International Advisory Board took more initiative — always helpful — than we had originally asked. The International Advisory Board was particularly helpful in the process of choosing section editors. Some of its members assisted us ably as we attempted to make the Encyclopedia as international as possible and also in dealing with special problems that are part of a large project with close timelines. Thus, we remember a few occasions where members of the International Advisory Board helped us with their substantive and social competence to deal with matters of editorial disagreements. Because of the overall quality, collaborative spirit, and professional responsibility of our section editors, these events were rare indeed, but dealing with them required masterful and accelerated input. We appreciate the collegiality that members of the Board displayed when called upon in these special circumstances.

In addition, and as described in the Introduction, there was a host of esteemed colleagues who gave us advice on numerous questions such as author and editor selection, organizational matters, topics for entries, content and quality of selected articles, substantive and methodological niches to be covered, as well as last-minute author replacements. The number of such individuals is large indeed, and most likely, significantly larger than the list presented below. There were too many short, but nevertheless significant collaborative encounters that we likely did not deposit into our long-term memory or written documentation. We apologize for such oversights.

In this spirit, we appreciate the advice given in the three planning meetings in Stanford, Uppsala, and Dölln/Berlin by the following scholars: Peter Behrens, Burton Clark, Gordon Clark, Lorraine Daston, Meinolf Dierkes, Jean-Emile Gombert, Torsten Husén, Gérard Jorland, Ali Kazancigil, Wolfgang Klein, Gardner Lindzey, Renate

Mayntz, Andrew Pettigrew, Denis Phillips, Marc Richelle, Ursula M. Staudinger, Piotr Sztompka, Eskil Wadensjö, Björn Wittrock, and Robert Zajonc.

We would like to extend special thanks to Laura Stoker, who pinch-hit for Nelson Polsby (section editor for Political Science) who was unable to attend the meeting of section editors in April 1998; and to Linda Woodhead, Senior Lecturer in Religious Studies, Lancaster University, who assisted David Martin with editorial work at all phases for the section on Religious Studies.

We also acknowledge the help of scholars who advised Smelser and Baltes at the stage of pulling together the entry lists, proposing authors, and occasionally reviewing the content and quality of articles submitted.

Smelser thanks: Jeffrey Banks, Peter Bickel, Edgar Borgatta, Charles Camic, Jennifer Chatman, Jean Cohen, Michael Dear, Pierre Ducrey, Eckart Ehlers, Sylvie Faucheux, Steven Guteman, Frank Furstenberg, Helga Haftendorn, Peter Katzenstein, David Laibson, Stephan Lauritzen, Douglas McAdam, Eleanor Maccoby, Phyllis Mack, Cora Marrett, Douglas Massey, Donald Melnick, Harvey Molotch, Lincoln Moses, James Peacock, Trond Petersen, Andrew Pettigrew, Alejandro Portes, Matilda Riley, István Rév, John Roberts, Dorothy Ross, Rob Sampson, Fritz Scharpf, Melvin Seeman, James Short, Fritz Stern, Carol Swain, Ann Swidler, Ken'ichi Tominaga, Charles Tilly, Wolfgang van den Daele, Sidney Verba, Margaret Weir, Thomas Weisner, and Jennifer Wolch.

Baltes is very grateful to: Nancy Andreasen, Gerhard Arminger, André-Jean Arnaud, Jens Asendorpf, Jan Assmann, Margret Baltes (deceased), Jürgen Baumert, Peter Behrens, Manfred Bierwisch, Niels Birbaumer, Peter Bloßfeld, Walter Borman, Robert F. Boruch, Mark Bouton, Michael Bratmann, David Buss, Shelley Chaiken, Lorraine Daston, Juan Delius, Marvin Dunnette, Georg Elwert, Helmut Fend, Hans Fischer, Peter Frensch, Alexandra M. Freund, Dieter Frey, Jochen Frowein, Gerd Gigerenzer, Snait Gissis, Peter Gollwitzer, Ian G. Gotlib, David Gyori, Heinz Häfner, Helga Haftendorn, Giyoo Hatano, Adrienne Héritier, Theo Herrmann, Otfried Höffe, Ludger Honnefelder, Paul Hoyningen-Huene, James Huang, Günther Kaiser, Heidi Keller, Martina Kessel, Gábor Klaniczay, Wolf-Hagen Krauth, Achim Leschinsky, Karen Li, Shu-Chen Li, Ulman Lindenberger, Elizabeth Loftus, Gerd Lüer, Ingrid Lunt, Hans J. Markowitsch, Laura Martignon, Randolf Menzel, Dietmar Mieth, Susan Mineka, Setsuo Miyazawa, John R. Nesselroade, Claus Offe, Vimla Patel, Meinrad Perrez, Rosa Lynn Pinkus, Robert Plomin, Neville Postlethwaite, Thomas Rentsch, István Rév, Peter Roeder, Richard Rorty, Hubert Rottleuthner, Peter Schäfer, Heinz Schuler, Norbert Schwarz, Richard J. Shavelson, Joan E. Sieber, Burton Singer, Wolf Singer, Edward Smith, Hans Spada, Günter Spur, Rolf Steyer, Michael Stolleis, José Juan Toharia, LeRoy B. Walters, Elke U. Weber, Peter Weingart, and Reiner Wimmer.

There was one more group that played a special role in the editorial review (see also Introduction). Baltes was assisted by a team of colleagues who provided expert input to the section editors and to him during final review: Gregor Bachmann, Alexandra M. Freund, Judith Glück, Wolfgang Klein, Olaf Köller, Shu-Chen Li, Ulman Lindenberger, Ursula M. Staudinger, and Christine Windbichler. Their expertise in helping us to ensure quality is gratefully acknowledged.

The day-to-day organizational work of the editors in chief occurred at their respective research centers — the Center for Advanced Study in the Behavioral Sciences and the Max Planck Institute for Human Development in Berlin. Smelser singles out Julie Schumacher, his main assistant in the project, for her organization of the meeting of section editors, and her superb coordination of the flow of correspondence and manuscripts over several years. She remained firm when the rest of us were faltering, and displayed the greatest efficiency, intelligence, and good cheer. Smelser also relied on periodic help from Leslie Lindzey, Kathleen Much, Jane Kolmodin, and Anne Carpinetti. Michelle Williams of the University of California, Berkeley, served as his main editorial assistant for nearly 2 years, going over all entry manuscripts from the standpoint of readability, and carrying a great part of the cross-referencing work; her judgment was always the best, and Smelser is forever indebted to her.

At the Max Planck Institute for Human Development, and aside from Julia Delius (see below), Baltes expresses his deeply felt thanks to the main secretarial staff in his office (Helga Kaiser, Romy Schlüter, Conor Toomey) who during the preparation of this Encyclopedia took on larger shares of responsibilities for other projects and occasionally helped out when the editorial office was overloaded. More directly involved in the day-to-day operation of the Encyclopedia was Penny Motley, who efficiently functioned as project secretary during the planning phase. During the main phases of the project, it was Yvonne Bennett who was responsible for secretarial and organizational matters. She deserves much applause for her superb and efficient help in the day-to-day running of the editorial office, making sure that all manuscripts and proofs were processed quickly, and also for assisting with the organization of various meetings. Not least, Baltes thanks the administrative office of the Max Planck Institute, and there especially Nina Körner and Karin Marschlich, for their competent work in managing the project budget, as well as Sabine Norfolk who handled most of the numerous fax

transmissions with ever present smiles and friendliness. Finally, in the Berlin editorial office, thanks are also due to Susannah Goss for her excellent work in translating individual articles into English.

Individual section editors wish to thank the following scholars who gave them substantive advice in their work: Richard Abel, Itty Abraham, John Ambler, Karen Anderson, Mitchell Ash, Alan Baddeley, Boris Baltes, Manfred Bierwisch, Michael Bittman, Sophie Bowlby, John Carson, Shelly Chaiken, Roger Chartier, François Chazel, Stewart Clegg, Carol Colby, Philip Converse, James Curran, Jerry Davis, Natalie Z. Davis, Peter Dear, Juan Delius, Michael Dennis, Josh DeWind, Sherry Diamond, Elsa Dixler, Georg Elwert, Howard Erlanger, Drew Faust, Malcolm Feeley, Nancy Folbre, Michael Frese, Angela Friederici, Lawrence Friedman, Bryant Garth; Victor Ginsburgh; Marcial Godoy, Frances Goldscheider, Calvin Goldscheider, John H. Goldthorpe, Reginald Golledge, William Graziano, Stephen Gudeman, Mauro Guillen, Doug Guthrie, John Hagan, Eric Hershberg, Steve Heydemann, Stephen Hilgartner, Judith Howard, William Howell, Jill Jaeger, Bob Kagan, Joe Karaganis, Roger E. Kasperson, Ronald Kassimir, Robert W. Kates, Wolfgang Klein, Hans-Dieter Klingemann, Bert Kritzer, Kay Levine, Steven Lukes, Michael Lynch, Akin Mabogunje, Stuart Macaulay, Donald MacKenzie, David Magnusson, Michael McCann, Sally Merry, Peter Meusburger, Sieglinde Modell, John Monahan, Kevin Moore, Gerda Neyer, Hiroyuki Ninomiya, Jodi O'Brien, Eva Oesterberg, Mark Osiel, James L. Peacock, Susan Phillips, Trevor Pinch, Wolfgang Prinz, Sheri Ranis, Harry Reis, Estevao C. de Rezende Martins, Marc Richelle, Leila Rupp, Gigi Santow, Austin Sarat, Simon Schaffer, Linda Scott, Tim Shallice, Seteney Shami, Ronen Shamir, Susan Silbey, Wolf Singer, Sheila Slaughter, Gerhard Strube, Ursula M. Staudinger, J. Stengers, Stephen M. Stigler, Michael Stolleis, Mark Suchman, Denis Szabo, Verta Taylor, Ashley Timmer, David Trubek, Leslie Ungerleider, Don Van Arsdol, Jakob Vogel, Rita Vörg, Judy Wajcman, Mary Wegner, Wlodzimierz Wesolowski, Steve Wheatley, Björn Wittrock, and Vincent Wright (deceased).

Section editors also thanked the following persons for their research assistance: Pamela Anderson, Susan Augir, Anja Berkes, Chantale Bousquet, Aida Bilalbegović, John Clark, Susanne Dengler, Kathrine Derbyshire, Annie Devinant, Casey B.K. Dominguez, Barbara Dorney, Elizabeth Dowling, Tracey L. Dowdeswell, Carolyn Dymond, Debbie Fitch, Susannah Goss, Verhan Henderson, Andrew Hostetler, Gudrun Klein, Heike Kubisch, Angie Lam, Ellen Lee, Valerie Lenhart, Kay Levine, Allison Lynn, Helena Maravilla, Carol B. Marley, Marion Maruschak, Michael McClelland, Rhonda Moats, Birgit Möller, Katja Neumann, Linda Peterson, Justin Powell, Paul Price, Xandra Rarden, Chris Reiter, Deborah Sadowski, Heidi Schulze, Heidi Sestrich, Keith Smith, Judith Thompson, Karen Varilla, Stuart Vizard, Danelle Winship.

It is difficult to single out one person as especially helpful. Despite the risks involved, we would like to highlight one person (see also Introduction). As shown in the front matter, beginning in the second year of the planning phase, Julia Delius served as our scientific editorial assistant. For our internal process of editorial review and management, Julia Delius was the mastermind of editorial coordination. Her work was simply outstanding.

Finally, we express our thanks to several individuals at Elsevier publishers whose work was both essential and helpful to us throughout. Barbara Barrett started the ball rolling for the entire Encyclopedia project, and was a master at negotiating out the fundamental arrangements at the beginning. Geraldine Billingham, as executive editor, also played an important role in the development of the project, as well as carrying the heavy responsibility for ensuring that all the financial and operational aspects of the project were realized. She executed this work with directness, skill, and tact. Angela Greenwell coordinated the editorial process with dexterity, calmness, and good judgment. Three persons were responsible for monitoring the progress of entries from Elsevier's side: Michael Lax for a time at the beginning; Jayne Harrison, who carried an overwhelming load of manuscripts month after month, and Helen Collins, who was responsible for the equally demanding job of shepherding the manuscripts through the entire production process. Ruth Glynn skillfully and imaginatively masterminded the development of the electronic version within Science Direct. We know how much the success of the Encyclopedia has depended on these individuals and their staffs, and our appreciation and admiration is here recorded.

Our expressions of gratitude and respect for the authors, section editors, reviewers, counselors, and editorial team, however, are not meant to distract from our own responsibilities as editors in chief. Let us hasten to add, therefore, that those whom we acknowledge deserve most of the credit but little of the blame for whatever shortcomings remain.

Neil J. Smelser
Paul B. Baltes
Palo Alto and Berlin
June 2001

INTRODUCTION

Alan Sica's article in this encyclopedia observes, "The urge to systematize and rationalize both common and esoteric knowledge has been strongly and continuously in evidence for at least 2400 years in the West" (Sica, 2015). Sica dates the origins of this urge to Plato's nephew Speusippus, who took up the challenge of Plato's call for an *encyclopedia* (from Greek words meaning 'general education'), and traces the urge though Pliny the Elder, Vincent of Beauvois, Francis Bacon, Denis Diderot, and a great many others. Today, an encyclopedia is simply a self-contained reference work "with two aims: to include up-to-date knowledge about a particular discipline or group of disciplines and to make this knowledge conveniently accessible" (Smelser and Baltes, 2001). Such are the aspirations of the present work.

Histories of the concept of an encyclopedia are widely available and need not occupy us here. Those interested in where the *International Encyclopedia of the Social and Behavioral Sciences* (IESBS) fits into the long history of encyclopedias will do well to consult the Sica article quoted above or the Smelser—Baltes 'Introduction' to the first edition of this work.

This is the second edition (2/e) of the IESBS. Elsewhere, I acknowledge my immense debt to the editors of the first edition, Dr Neil Smelser and Dr Paul Baltes. Without their perspective and template to follow in assembling the second edition, this version would have scarcely been possible. The very thought of an encyclopedia covering *all* the social and behavioral sciences, one that drew on scholars from *all* corners of the globe, is itself so audacious that one would hesitate even to begin without a pretty detailed road map to the terrain.

On the occasion of the publication of Robert E.L. Faris's widely acclaimed *Handbook of Modern Sociology*, Joseph Gittler was moved to ask, "With the plethora of new handbooks, reviews, and compendia in sociology, one wonders whether there is a need for yet another one." That question was posed almost 50 years ago; the ensuing half-century has been marked, as Sica says, by "an avalanche of reference materials the likes of which had never been seen in libraries prior to about 2000." So readers and critics are within their rights to ask: Why a second edition? Why now?

The first edition (1/e) was reviewed in *Contemporary Psychology* as "the largest corpus of knowledge about the social and behavioral sciences in existence" (Park, 2004). According to readily available data sources, IESBS 1/e has been cited nearly 6000 times in subsequent scholarly literature and has an h-index ($h = 24$) that would be the envy of many full professors. Citations are only one measure of impact, of course, and probably not the most important measure for a basic reference work intended more for students and a general audience than for practicing professionals. In addition to the thousands of scholarly citations, items from IESBS 1/e were 'hit' almost two *million* times on Science Direct between online publication in November 2002 and August 2014 — two million instances where IESBS 1/e was likely consulted as a basic reference source, to get quickly up to speed in a new area of research or to provide background for a paper or project, or just to satisfy a reader's curiosity. The first edition, in short, emerged soon after publication as a go-to reference work throughout the social and behavioral sciences. Michael Shanahan referred to the first edition as "the atomic bomb of reference works." It was thus an easy conclusion that the work had sufficient value to keep it alive and current.

In reading selected articles from the first edition, however, I was taken aback by how much and how quickly they had aged. The first articles I looked at were those pertinent to my own areas of research and in nearly every case, there was important recent work that I felt needed to be discussed. With the assistance of colleagues in other areas of the social and behavioral sciences, it became obvious that this was a general problem. To be sure, much of the material in 1/e has enduring value; indeed, roughly half the articles in 2/e are updated and revised items from the first edition. Still, it is sobering to realize just how quickly the frontiers of social science

knowledge shift and thus how quickly a basic reference source becomes dated. I am certain there are articles in the current edition that are already in need of some updating.

Smelser and Baltes enumerated six criteria that guided their decisions about what to include and what to leave out. The criteria are as follows:

1. secure knowledge, realizing that security of knowledge is a dynamic and relative term,
2. knowledge with balance and comprehensiveness,
3. knowledge that is integrative rather than fragmented,
4. knowledge that places the evidence into historical and theoretical context,
5. knowledge that highlights connections between topics and fields, and
6. knowledge that combines, where possible, theory and practice.

I would like to say I have followed these same criteria in determining the content of 2/e, but all six criteria have proved problematic in one or another way and thus deserve some comment in light of the present work:

1. What is secure knowledge today is apt to be recognized as wrong tomorrow. Many of our requests for updates to 1/e articles generated some response to the effect, "All of this is completely obsolete. We need to write a new entry from scratch." One would expect this to be true of areas of research such as behavioral genetics, say, or cognitive neuroscience or other fast-moving scientific fields, but it also turns out to be true of archaeology, history, and philosophy. The leading edge of research in *every* discipline threatens received wisdom; those who content themselves with received wisdom ('secure knowledge') will quickly find themselves behind the times. So our charge to authors was to focus less on the 'secure knowledge' in their respective fields and more on the cutting edge — the new perspectives, methods, findings, and issues that will animate social and behavioral science research in the coming decade.
2. Throughout the social sciences, the distinction between theory and ideology is sometimes difficult to discern, and so too the distinction between applied research and community or political activism. We need not invoke Max Weber's conclusions about the impossibility of a truly value-free social science to understand that ideological undertones and political preferences can often be detected in social science research work; sometimes, they are quite explicit. Nor is it much of a surprise to learn that many social scientists struggle, not always successfully, to distinguish between what they want the world to be and what the world in fact is. Such struggles are part of the process by which knowledge develops and are thus in evidence in many of the 2/e articles. It would be unwise to enforce by editorial fiat a consensus on issues that the social sciences themselves have yet to resolve.
3. The fragmentation of knowledge *across* disciplines is far more serious that the fragmentation of knowledge *within* them, although the latter is a problem as well. Many well-informed sociologists, for example, take pride in reading widely and can speak with some authority about what is going on in the field, even in areas of sociology that do not directly concern them. I assume this is also true of the other social and behavioral science disciplines and areas. But rare is the sociologist who is cognizant of work being done, say, in social geography *even when*, as is often the case, the fundamental problems, theoretical issues, and methodological approaches are similar. This is a widespread problem across the disciplines: The evolutionary psychologists do not know as much as they should about what the anthropologists are doing; the economists ignore a lot of pertinent work in sociology and political science; etc. For better or worse, disciplinary differentiation is an inherent element in the process of knowledge development and discovery, so this is a reality to be faced, not a problem to be solved. We dealt with this reality mainly in two ways: (1) Authors were encouraged wherever possible to think across rather than strictly within their disciplines. (2) Calling relevant work done in other disciplines to the reader's attention was a guiding principle for the choice of cross-references for each article.
4. Social-constructionist theories of knowledge would argue that knowledge does not become knowledge until it is placed in historical, cultural, social, political, and theoretical context. As put very simply and succinctly in the opening line of the famous text by Berger and Luckmann, "reality is socially constructed" (1966: 1). This is no less true of social science knowledge than knowledge in any other realm. Unfortunately, a great deal of what we think of as social science knowledge is based on biased samples of WEIRD people — that is, Western, Educated, Industrialized, Rich, and Democratic (Henrich et al., 2010). (The same point has, of course, been made by many others.) The WEIRD, thus defined, represent a rather exotic minority group judged by world standards, and the challenge for IESBS 2/e was therefore twofold: (1) to recruit non-WEIRD editors and authors where possible; and (2) to persuade all authors to incorporate comparative, cross-cultural, and

international themes and perspectives wherever it was possible to do so. This effort was more effective in some sections than in others. Moving away from nation-specific literature, themes, and results to a truly *international* (the I in IESBS) account of the social and behavioral sciences was an ever-present *desideratum* in my discussions with editors and authors.

Alas, an emphasis on cross-culturalism often brings to light that everything, or nearly everything, seems to vary by culture, subgroup, ethnicity or nation, and at that point the question arises whether social science generalization is even possible. Are there universals that cross all social groupings? Or does social science dissolve into a mist of group-specific particularities that adduce no general principles? That hardly seems desirable. Yet myopic and ethnocentric fixations on one's own society or culture are scarcely to be encouraged either.

The worst offenders in this regard tend to be social scientists from the USA (and from the West more generally), who, of course, also comprise the largest share of editors and authors for IESBS 2/e. True, as with greenhouse gases, the USA (and the West) also produce the largest share of the world's science, social and otherwise, and so it is inevitable that they also represent the largest share of IESBS 2/e contributors. The Swedish social anthropologist Ulf Hannerz wrote about this very issue in his marvelous essay, "Editing Anthropology" (Hannerz, 2010). Hannerz quotes a Canadian anthropologist who said of the "neighborly presence" of US anthropology that it was like being "in bed with the elephant." The same is true of most or all of the disciplines covered in this work. But then in a passage remarkable for both its insight and its generosity, Hannerz remarks, "No doubt tensions and conflicts may arise out of this situation, but perhaps it is better to understand that the elephant cannot help being an elephant, and that it makes sense for it, in its habitat, to behave in elephantine ways. A well-trained elephant, too, can do a lot of good, such as in carrying heavy loads." So if the elephant that is Western social and behavioral science has been pressed to carry the heavier load in these pages, that is, the price to be paid for being an elephant in the first place.

The larger issue here is that the social and behavioral sciences, which were largely birthed in the West, in Europe and the United States, mainly address a trans-Atlantic scientific dialogue, a dialogue that is carried out almost exclusively in English. Indeed, throughout much of the world, a scientist's stature is indexed in part by his or her success in publishing in English. Publications in the native language are simply *assumed* to be inferior. The main exceptions, tellingly, are French and German social scientists whose native-language publications are valorized. A Dutch or Portuguese or Hungarian social scientist who only published in the native language would be seriously punished in merit and tenure reviews. Elsevier's citation database Scopus *requires* English-language abstracts before a journal will even be considered for inclusion. And English (with American spellings) is likewise the official language of this encyclopedia. No resources were made available to get articles submitted in other languages translated (although several such articles were submitted). Inevitably, this biases the encyclopedia's coverage in favor of social science addressed to the trans-Atlantic dialogue. Consequently, a great deal of excellent social science published in Spanish, or Mandarin, or Farsi, or any of the other world languages, is overlooked.

That said, steps were taken to improve the internationalism of the encyclopedia's coverage throughout the 4 years of its development. To begin, I sought area and section editors from around the globe and urged them whenever possible to seek international (vs strictly Western) authors. Articles were often returned to their authors with explicit instructions to add international coverage. And when all efforts failed and we ended up with articles that were unmistakably restricted to a single nation in their coverage (frequently but not always, this was the US), I indicated the national focus in the article subtitle. Still, a great deal more WEIRD social and behavioral science remains in these pages than would be desirable in an *international* encyclopedia. In a later section, I give the national breakdown of everyone involved in this project.

5. An encyclopedia that "highlights connections between topics and fields" is easier to envision than to accomplish. Criterion (3) above speaks to the disciplinary fragmentation of our social science knowledge. William Easterly, the NYU economist, has written about the 'tyranny of experts' but the tyranny of the disciplines is an equal problem, a tyranny sanctified by the very academic structure of the modern university, where the separate and often warring colleges are each comprised of assorted departments, the latter representing basic academic disciplines. Interdisciplinary programs are almost invariably relegated to various centers, institutes, or specialized research laboratories — in short, to the periphery of the university's power structure. And while everyone *says* they want to encourage multi- and interdisciplinarity, very little is done to make that happen. Instead, departments remain as the fundamental unit of academic organization.

   Hortatory admonitions to editors and authors have made IESBS 2/e somewhat more interdisciplinary than its several predecessors, but in the end, the disciplinary emphasis in many of our articles would be hard

to overlook. Still, there are many sections of the work that were clearly developed with interdisciplinarity in mind and in which one finds interdisciplinary social science at its current best: environmental and ecological sciences; health; life course; sexuality; GLBT studies; public policy; evolutionary sciences; war, peace, violence, and conflict; and genetics, behavior, history, and society are a few sections that come immediately to mind.

I am particularly pleased with the extensive coverage given in 2/e to the interactions between the biological and social sciences. Harry Whitaker once remarked in a private e-mail that "we are all witnesses to the marriage of biology and the social sciences." Many of the articles found here are offspring of that marriage. And those articles leave little doubt that the future offspring of this marriage will be among the most exciting and insightful social science products of the coming decade.

The social sciences once resisted everything biological as rank reductionism; in addition, the social scientists have always feared that a mature and complete biology would eventually drive us out of business. Articles included in IESBS 2/e make it clear that 'nature' versus 'nurture' was the wrong question from the very beginning, that what we need to understand is how biological inheritance and social and cultural forces *interact* to produce individual and collective outcomes. This is where a lot of the interesting action in the social sciences is going to be in the coming years.

6. The coverage of the practical or applied sides of the various disciplines has been increased in this edition, so the applied content of 2/e certainly exceeds that of its predecessor. New to this edition is the entire section on applied social and behavioral sciences; also new is our large section on social work and the separate section on applied, industrial and organizational psychology. But as Sara Strickhouser and I say in our article on the history of applied social research, "The history of 'applied social science' is indeed the history of the social sciences themselves" (Strickhouser and Wright, 2015). All of the social sciences in their modern form were birthed in the post-Enlightenment effort to understand why people, their institutions and society as a whole were as they were — why greed was more visible than generosity, why oppression was more common than freedom, why inequalities of various sorts characterized every social institution. To the founders of the disciplines, the modern distinction between basic and applied scientific concerns would have seemed meaningless, as indeed it was.

The Planning Phase and Editorial Structure

Elsevier's original acquisitions editor for this project, Scott Bentley, discussed the broad outlines of our attack on IESBS 2/e with me in a series of phone calls in the early months of 2010. By May 2010, certain of these outlines had come into sharp relief. There would be a single editor in chief with a tier of 'responsible lieutenants' to assist. These lieutenants started out as advisory editors but soon morphed into the 10 area editors in the final editorial structure. Each area editor would in turn oversee various sections and each section would have its own editor or editors. The original plan was that the area editors would each be responsible for approximately 400 articles and each section editor responsible for about 100 articles, so that no one would have an excessive amount of work compared to everyone else. In the end, however, some sections required more articles and others fewer, so the areas vary from fewer than 300 to more than 600 articles, and the sections vary from fewer than 30 articles to well more than 200.

Prior to my first discussions with Scott Bentley, Elsevier had commissioned about 20 'market surveys,' roughly half from professional librarians and the other half from academics, each focused on 'what was right and what was wrong' with the first edition. The most insistent demand that surfaced was for a fully electronic, computer-searchable work either in addition to or instead of a print version. In the end, both an e-version and a print version are being made available. But there were also consistent concerns expressed about spotty coverage of some areas: no coverage of social work to speak of; inadequate coverage of accounting, marketing, and business; no separate section of criminology; haphazard coverage of applied topics and concerns; and so on. And there were the predictable concerns about undue Western domination of the work.

Working from the 1/e Table of Contents and this stack of 20 surveys, I tinkered for a few months with how best to expand coverage to address the concerns our reviewers had expressed; the result was (more or less) the editorial structure shown elsewhere in the front matter of this work. Thus, the 53 sections of 2/e are basically the 39 sections of the first edition plus sections that were added to cover important emerging areas of research interest (e.g., gay, lesbian, bisexual, and transsexual studies) or to provide deeper coverage of disciplines and subdisciplines that the first edition treated lightly if at all (applied social and behavioral sciences, social work). A

few of the first edition sections were eliminated entirely: specifically, integrative concepts and issues (something of a catch-all category for 1/e articles that were highly interdisciplinary or simply did not fit anywhere else) and gender studies (gender is now so thoroughly integrated into the research and thinking of all the social and behavioral science disciplines and subdisciplines that a separate section was unnecessary and somewhat retrograde). Others were altered or expanded in significant ways (organizational and management studies, for example, became the second edition section on management, organizations, business, marketing and finance; expressive forms evolved into the 2/e section on culture and the arts; linguistics was subdivided into three separate sections; etc.) And some subdisciplinary areas that were part of other sections in the first edition were given their own sections in the second (life course studies; sexuality; criminology; labor studies; and war, peace, violence, and conflict are the most prominent examples), just to ensure adequate coverage.

The Introduction to 1/e (Smelser and Baltes, 2001) discusses at great length the intellectual architecture of the first edition and its evolution; the agonizing decisions about rules for the biographical articles; whether to organize the work by discipline, by concept, by an a priori taxonomy of social science knowledge, or in some other manner; and related structural matters. What resulted in 1/e was something of a hybrid model with some sections clearly representing specific disciplines, others representing 'overarching topics,' still others representing 'intersecting fields,' and so on. My task was far less challenging: I thought the architecture of the first edition served its purposes admirably and so I adopted it wholesale for the second edition, with the small modifications noted above.

While each of the 53 sections of 2/e has some more or less obvious justifying logic or substantive or disciplinary coherence, their arrangement into the 10 areas of the second edition does not. As already indicated, decisions about what sections to include and exclude were made very early in the development of the second edition, based on what was in the first edition, what Elsevier's marketing surveys suggested as significant lacunae, and my own sense of things. The arrangement of the sections into areas came later and was dictated largely by the interests and expertise of those who had been persuaded to sign onto the enterprise. Thus, all the Linguistics sections are in Area Five along with the cognitive and neuroscience sections because Harry Whitaker at Northern Michigan University had been a linguist first, a neuroscientist second, and a historian of psychology third. Likewise, Area Eight contains its seemingly chaotic hodgepodge of evolutionary sciences, genetics, religious studies, science and technology studies, and law because these happen to be the fields of interest of the redoubtable Barbara Prainsack of King's College, London, whose editorial talents are as deep as her interests are broad. Simplifying only slightly, section editors were chosen for their substantive expertise in particular areas of research (as well as their international or cultural 'range'); the plan was that section editors would review each of their articles for completeness of coverage, currency, fairness, and the like. In contrast, area editors were chosen for their breadth of interest and knowledge spanning multiple sections – people who by nature, experience, and training would be good at seeing the big picture. The role of the area editors was to assure that the articles were at least modestly international and interdisciplinary and formed some sort of coherent whole.

As laid out in an early e-mail to one of the area editors, "In my mind, Advisory [Area] Editors are generalists and Section Editors are content specialists. The Section Editors need to bring breadth of knowledge to their responsibilities, of course, but the primary job requirement is expert understanding of the particular field or section. We need section editors who can commission pieces that adequately review past developments in the subject area, but who can also shape their portfolios to identify major unanswered questions and new research developments." This was the general model followed throughout the recruitment process.

The approach just sketched inevitably left a residual area made of up sections that none of the other area editors were willing or able to claim. That proved to be Area Ten. A very large number of scholars from various disciplines and world regions were approached about serving as the Area Ten Editor. All demurred until I approached Martin Bulmer of the University of Surrey, who served the project for about a year but was unable to continue and subsequently left the Board. So for the final year of the project, the editing of Area Ten was done mainly by me.

The online subject classification for IESBS 1/e did not correspond precisely to the sections of the first edition; the subject classifications listed articles by broad general topic regardless of which 1/e section developed them. So for the first year or so, my assistants and I labored to assign every 1/e topic to one of the 53 2/e sections. With 53 sections to populate with articles and about 4000 articles to classify, the process of assigning articles to unique sections occupied huge amounts of time and generated endlessly complicated spreadsheets. (After about a year of this, a document surfaced in the Elsevier archives that showed exactly where each 1/e article had originated.)

Along with populating the 2/e sections with articles, searching for area and section editors occupied a major part of the early going. The original idea was to identify the 10 area editors first and then enlist them in the

search for their section editors, but in fact, these processes were simultaneous and were about half-completed when the two planning meetings were held: the first in San Diego on 19 and 20 May 2011; the second in London on 5–7 June 2011. Although not part of the plan, the first meeting was mostly attended by area editors and the second, by section editors.

The agenda for both meetings was largely identical: achieve clarity on the respective roles of the various editors; solicit advice on filling the unfilled editorial slots; get buy-in on the project *mantra* (internationalism, interdisciplinarity, inclusiveness!); explain the relationship between the first and second editions (e.g., that all 1/e authors would be offered the opportunity to update their articles); explain the process of assigning articles to sections; and the like. In almost all cases, consensus was quickly forthcoming.

The largest substantive change in the second edition is the treatment of psychology. (Whether measured by students, practitioners, professors or programs, psychology is the largest of the social and behavioral sciences.) In the first edition, the whole of psychology was contained within four large sections: clinical and applied psychology; developmental, social, personality, and motivational psychology; cognitive psychology and cognitive science; and behavioral and cognitive neuroscience. Cognitive science and neuroscience are, of course, rapidly growing sectors of the psychological discipline and it seemed appropriate to devote an entire area of the second edition to them. This area contained seven separate sections (three of them devoted to linguistics). And the 'softer' psychological sciences were placed in a separate area comprised of eight sections (including psychiatry and social work). These changes were made to assure that 2/e had adequate coverage of the entire psychological enterprise (a concern that was raised in some of the reviews of 1/e).

The structure of the editorial team was developed to serve two purposes: first, to divide up the labor into manageable parts; and secondly, to assure that every article in the final product would be reviewed by at least three scholars: the respective section editor, area editor, and the editor in chief. Since we were all aware of one another's identities throughout, the review process was not blinded, but every article in this work has been thoroughly peer-reviewed and vetted. In many cases, these articles have been through four, five, six, or even more revisions before being accepted for inclusion in the work.

Recruiting Editors and Authors

IESBS 2/e faced two different recruiting tasks: recruiting editors and recruiting authors. As indicated elsewhere, the original plan was that I would recruit area editors largely from my own personal networks and they in turn would recruit their section editors. In practice, the process was much more convoluted. First off, many of my 'first choice' candidates were hesitant to involve themselves in such a daunting and ambitious project. In some cases, an initial agreement to come aboard was followed a few weeks or months later by withdrawal as the true scope of work came into sharper focus. Some people that I tried to recruit as area editors demurred but agreed to serve as section editors; in other cases, candidates for area editors were nominated by section editors. In a couple of cases, there was a complete team of section editors prior to the successful recruitment of a corresponding area editor. And so on. The process of assembling an editorial team for the project was by no means linear.

Personal networks – mine and those of the people I persuaded to sign on – were the largest single source of ideas for other editors, by far. But personal networks tend to follow disciplinary and national lines and become rather quickly exhausted. In selecting both editors and authors, it was of course essential that all relevant perspectives be covered and that the breadth of fields was adequately represented. So other sources of ideas were tapped: the expertise of the Major Reference Works team at Elsevier; editorial boards of leading journals in the respective fields; Google Scholar citation counts; the knowledge and networks of people who had been involved in preparing the first edition – basically, anywhere names of top scholars in particular areas could be located. I did not keep systematic track of the number of people approached, much less of the outcomes; but in reviewing my e-mail archives from the early period of the project, I probably asked (on average) somewhere between six and eight prospects before I found someone to agree (an average that was highly variable across the areas and sections).

In the initial plan, area editors would recruit their own section editors and the section editors would in turn recruit their own authors, but the reality was again different. Inevitably, my negotiations with prospective editors (both types) would often result in a declination of the editorial role but an offer to write an article on a particular topic (or topics), offers I readily accepted. So in some cases, I had committed authors of particular articles well before I had the corresponding section or area editor in place. And many of the section editors likewise leaned on their area editors and on me for author suggestions, contacts, and outreach. So all the editors

were involved in locating willing authors (and not coincidentally, in making suggestions for articles to be included in the final work).

No one was asked to keep precise statistics on how many authors were sought before an agreeable author was found. My sense is that the 2/e editors had a somewhat tougher time with this than the 1/e editors had (but on the other hand, the 2/e editors had all the 1/e authors to work with, which Smelser and Baltes certainly did not have). The 1/e editors report that about 60% of those invited to write articles agreed to do so on the first 'ask' (with equivalent success rates in each subsequent 'ask'). In 2/e (or so I would guess), the success rate was probably closer to 50% and possibly even lower. They also report that something in excess of 90% of those who agreed to write for 1/e in fact contributed "acceptable entries in time to be included…" In the 2/e case, we found ourselves still soliciting authors within a few weeks of the submission deadline and some dozens of authors pulled out of the project at the last minute. Still, when all the dust settled, there were just about 800 articles planned for both editions that never materialized and both editions ended up with just fewer than 4000 articles. Perhaps these are 'natural limits' for a work of this sort.

Biographies*

In the Introduction to 1/e, Smelser and Baltes provided a short history of and rationale for the decision to include a limited number of biographical articles (150 of them, to be exact). This was evidently a controversial and contested decision since some of those associated with 1/e felt that biographical articles had no place in an encyclopedia focused on substantive knowledge (versus the personalities of those who produced it). As Newton said (paraphrasing a passage from Bernard of Chartres), "If I have seen further, it is by standing on the shoulders of giants" (a passage made famous among social scientists by Robert K. Merton's *On the Shoulders of Giants* (1965)). In other words, discovery is only possible because its discoverer is able to refer to knowledge already gathered and accumulated by his or her predecessors; and since all discoveries – small and large, substantial and minor – contribute to the production and accumulation of knowledge, singling out particular scholars for special attention would be both pointless and invidious.

This position, although understandable, was abandoned in the first edition and remains so in the second, largely because it is not possible to understand the social sciences without knowing the individuals who contributed to it. C. Wright Mills once defined the sociological imagination as the intersection of biography and history (Mills, 1959). To know the social sciences therefore requires biographical and historical knowledge. The social sciences are distinguished from the physical and biological sciences in the way they produce knowledge because individual human beings, including social scientists, invest meaning in their actions. Only through understanding the meaning that individuals give to their actions are social scientists able to provide explanations of human behavior and its outcomes. And what applies to social action in general applies to the production of social science knowledge as well. It thus makes sense to include biographical accounts of social science personages who have been particularly distinguished in making sense of human action and have in turn made major contributions to social science knowledge. To acknowledge individual social scientists with biographical articles is also to acknowledge their special and particular insights.

Once the decision was made to include biographies in 1/e, the next major decision was whom to include and whom to leave out. Two arbitrary but defensible principles governed these decisions: (1) the total number of biographies was not to exceed 150 (chosen because it seemed like a manageable number) and (2) only biographies of the dead would be included. The 1/e section editor for biographies, Karl Ulrich Mayer, consulted handbooks and encyclopedias, asked other section editors to name and rank the most important names in their respective disciplines, ran citation checks, and finally submitted a consolidated list to various experts for review. This resulted in some additions and some deletions and in the end 147 biographies made it into the first edition.

Instructions to authors writing these biographies directed them to include "a brief sketch of the major dates and events in the life of the biographee," to describe "the major contours of the [person's] substantive contribution," and to highlight the "importance and relevance of the biographee's work for the social and behavioral sciences." Largely the same instructions were given to 2/e biographers.

The selection criteria for 2/e were very different. First, on the reasoning that well-done biographies of leading figures is one of the things that draw readers to a work such as this, the total number of biographies was

* My thanks to Andreas Hess for drafting this section of the Introduction.

increased by more than 100 (to just over 250). In a major departure from 1/e, much of the increase is made up of biographies of the living. The 1/e restriction that excluded living persons resulted in anomalies that we thought needed to be addressed. As life expectancy has expanded in the twentieth and twenty-first centuries, so have the life spans of social scientists. Claude Levi-Strauss, to cite one obvious example, lived to the age of 101 years. When 1/e was published, he was in his 90s, was widely cited, was recognized universally as a modern classic, indeed a genius, of social anthropology – and yet, owing simply to his longevity, he was not included in the 1/e biographies. Biographies of, for example, the economist Herbert Simon, the political economist Albert O. Hirschman, the sociologist and philosopher Jürgen Habermas, and the linguist Noam Chomsky were all excluded for the same reason; indeed, Habermas and Chomsky still live as this is being written (Fall, 2014). In all these cases, the major works had been produced decades earlier, their major imprints on the social and behavioral sciences were already evident, their eventual inclusion in works such as this was inevitable. Are readers to be deprived of accounts of their lives, times, and contributions just because they have survived into deep old age?

Once the decision was made to include biographies of the living, however, it was not always easy to decide who among the living merited inclusion. Often the editors had to make decisions on a case-by-case basis, frequently in extended consultation with colleagues or experts in the field. Criteria used to make these decisions were whether the potential biographee had a reputation beyond one culture, nation, or language group; whether there was a record of sustained production over several decades; and whether there was an impact beyond the confines of a single discipline. These criteria reduced our list of suggested biographees considerably. Early lists of candidates numbered as many as 200 new names (in addition to the 147 biographies included in 1/e). In the end, as noted earlier, somewhat more than 100 new names were added.

In a few cases, persons were included that arguably did not satisfy our inclusion criteria. One such is Raul Hilberg, who became famous mainly for having written one very important book, *The Destruction of the European Jews* (1961). Hilberg's book is still regarded as the seminal work in Holocaust studies, a field of research that came to prominence much later; we felt that his signal contributions to Holocaust studies merited a biographical article. Much the same could be said, perhaps, of André Gorz, a well-known social theorist from France, and Albert Memmi, whose work is on colonialism, anticolonialism, and racism. These and other examples could and probably will raise questions about the porousness of our criteria. Whether we were right in giving 'trespassers' their space is open to debate. In any case, whether Hilberg, Gorz, Memmi, and others do or do not merit their biographies is for readers, not us, to decide.

Other important changes in the 2/e biographies section include, first, a conscious effort to attain a better gender balance, including more women both as biographees and as authors; and second, expanding the biographies both geographically and culturally. In the end we made some inroads in both respects but fell short of our internal goals. One of the main reasons for this is that any encyclopedia must, in the first instance, be true to the disciplines it represents. This means being true to the real status of important players, their networks and disciplinary power relations, and their academic capital in their respective fields and beyond. Change in these respects has been noticeable; certainly, the growth of the social sciences in Asia has been remarkable; and in most disciplines, the proportional presence of women has increased. But modest change in the right direction does not a revolution make. Too many nonwhite, non-Western, and nonmale practitioners are still being left out on the disciplinary peripheries and are not fully represented – not in their home disciplines and not in our encyclopedia either.

We state this fact with regret. In many cases, the limiting factor is not excellence but simple visibility. Being part of the trans-Atlantic social science dialogue and engaging this dialog mainly in English translates into more visibility, as discussed earlier. This gets a scholar on the radar screen. Equally excellent work engaging other intellectual dialogues in languages other than English does not. A great many outstanding scholars have thus gone unrecognized in 2/e for precisely this reason. That being said, strenuous efforts were made to make the 2/e biographies more inclusive. Among those included are the Argentinean educationalist Sarmiento, the Brazilian sociologist Cardoso, and the Japanese political scientist Maruyama, to name just a few. This is, however, 'just a few' of the many dozens of prominent social and behavioral scientists 'out there' whom we would have included had we been given more time and more resources (to get non-English works translated, for example). We do feel that we have made some important inroads and beg the reader's understanding of the limits within which we worked. We can only hope that the next edition will strive for more inclusiveness and better representation than we were able to achieve.

Another entirely new feature in the 2/e biographies is the series of 'collective biographies.' In many instances, the intellectual lives of individuals who work in research groups intersect and form a network that makes the

entire group (or paradigm) successful. Examples include articles on the Durkheimians, the Annales School, the Frankfurt School, and several others.

As indicated earlier, instructions to authors were changed little from 1/e. All authors were asked (1) to include the most important biographical facts (country of origin, generation, education, influences, other formative experiences, networks, etc.); (2) to list the most important output (discoveries, publications, etc.) and to briefly discuss the subject matter and content of the most important publications or discoveries; (3) to look at the lasting impact of the person and his or her work (if possible, beyond just one discipline, language group, or culture); and (4) to provide a bibliography of primary and secondary sources related to the biographee and his or her work. Most authors stuck to these guidelines.

Finally, we state for the record that there are a number of important social and behavioral scientists that we would have liked to include but for whom we were unable to find a proper biographer. The search for biographers went on for nearly 4 years. In many cases, our first-choice author agreed at once, but in other cases, we approached four, five, or even more people before an agreeable author was found. And in about two dozen cases, no such author was ever found, with the result that a deserving person's biography had to be dropped. Forgoing a case-by-case discussion of these deletions, let it be simply noted that this is why we have not included biographies of people such as Amartya Sen, the economist and social philosopher; Raymond Boudon, the French sociologist; Ronald Dworkin, the legal theorist; Avishai Margalit, the philosopher; or a collective article for the British Marxist historians (Eric Hobsbawm, E.P. Thompson, Christopher Hill, and Perry Anderson). Perhaps our most regrettable omission is Neil Smelser himself, for whom no biographer could be found despite at least a dozen attempts. (Paul Baltes's biography is included.) Neil is one of the giants on whose shoulders we all stand.

Redundancy

I mentioned earlier that in the beginning of the project, there was no 'map' linking each of the 1/e articles to its respective 1/e Section. Our efforts to create such a map invariably bogged down every time we hit an article that could plausibly belong to any of several sections, which was often. Obviously, it would have been possible to force every article into a 2/e section, but at the time it seemed advisable to involve the editors themselves in these decisions. So on numerous occasions, I distributed lists of 'orphaned' articles (articles for which no home had yet been designated) to the area and section editors, asking for foster parents to volunteer. Eventually, of course, every article found a home, but at a relatively late date in the process, I became aware that a few dozen articles had found more than one home. That is, some of the editors adopted articles without filing the appropriate paperwork with the editor in chief! In such cases, the result was two articles on the 'same' topic. (The 2/e Table of Contents was scoured multiple times looking for precisely these kinds of duplications but in the end, several proved elusive.)

In the large majority of cases, the content of the 'duplicate' articles was sufficiently distinct that both articles were retained, often with some retitling to help readers differentiate between them. For example, readers will find two articles on 'social identity.' One was recruited for the section on social psychology; the other for the sociology section. With rare exception, the two articles discuss different aspects of social identity from entirely different disciplinary angles; indeed, the two articles share only a small handful of common references. So it was an easy decision to retain them both: one appears here as Social Identity in Social Psychology; the other as Social Identity in Sociology. Careful readers will find perhaps a score of similar cases in the encyclopedia.

Alas, in a few regrettable cases, the overlap between duplicate articles was so pronounced that one of the articles had to be deleted. Since by the time these problems surfaced the articles had (often) been written and rewritten several times and had been accepted by both the section and area editors, the last-minute decision to delete a redundant article was painful. My sincere apologies to the authors involved.

Some redundancy in a work of this scope and aspiration is not only inevitable, it is probably also desirable. A reader interested in, say, social inequality will (one hopes) want to know what the sociologists, anthropologists, economists, and geographers all have to say about that topic. And if a few of the many articles on the topic say more or less the same thing, then what harm is done? Editors at all levels were asked to be alert to redundancies across articles and the editorial record shows that many were. That being said, quite a bit of topical redundancy no doubt remains, and that is not (in general) a matter of concern. It is what Smelser and Baltes refer to as the "inevitable residue of overlapping."

The Review Process

Once the table of contents had stabilized, each of the editors was asked to review the 1/e articles assigned to their section or area and come to various decisions. In some cases, 1/e articles could be reprinted more or less 'as is,' with perhaps some updating of references for readers seeking entry points into the current literature. This was especially the case with what were eventually designated as 'legacy articles,' e.g., Gabriel Almond's article on Civic Culture, James Gregor's article on Dictatorship, &c. In other cases, the 1/e articles needed some updating to be suitable for 2/e, either by their original authors when available or by others recruited specifically for the purpose. The general rule was that all 1/e authors would be offered the opportunity to do the updates themselves, and that other authors would be sought in the event of the original authors' declinations. In still other cases, the 1/e article was so obsolete than an entirely new article would be required. And then finally, the review of 1/e articles often revealed areas of current research that were inadequately covered; in these cases too, completely new articles would be sought.

Where appropriate, the relationship between the 1/e and 2/e versions of an article is spelled out in the article tagline. In many cases, there were issues of authorship to resolve — a 1/e article written by *X* and completely revised by *Y* is *Y*'s article although *X* might be identified in the tagline; but what of an article written by *X*, now deceased, and only modestly revised and updated by *Y*? Every decision rule that I formulated to resolve such issues soon confronted an exceptional case where the rule did not seem to apply. So in the end, the only workable rule was that everyone should get proper credit for their intellectual property, whether prime author or reviser, whether living or dead. If exceptions to this rule have crept into the final product (as they almost certainly have), I offer my apologies to those whose work has been slighted or improperly recognized. Deciding on proper authorship for many of our articles was a far more involved and difficult task than expected.

The section editors formed the first line of editorial defense and were the ones to whom article drafts were originally submitted. The section editors read and commented upon the draft articles and returned them to authors for revision. It is a rare article that appears here in its original form: on average, articles were revised two or three times before being sent to the area editors and subsequently on to me; in many cases, it was more like five or six revisions, with subsequent revisions at the request of the area editors and the editor in chief. And in some cases, articles were submitted to outside readers for independent review. As I stated earlier, the reviewing process was not blind, but it was quite thorough, as is reflected in the exceptional quality of the final product.

Internationalism and Inclusivity

A truly *International* Encyclopedia of the Social and Behavioral Sciences would of course require a global network of editors and authors *and* a commitment to internationalize the content of the work wherever possible. With respect to the editorial team for 2/e, this was definitely realized. The section editors and editors in chief who produced the first edition were drawn from only nine countries: The United States, Germany, Italy, Canada, Sweden, Australia, France, Switzerland, and the UK. Two-thirds of those editors were from the USA and only 13% were women. Area and section editors for 2/e represent 21 countries, US scholars make up only 38% of the total, and women comprise 36%. Thus, the proportional representation of women among the editors was nearly tripled in 2/e over 1/e while the predominance of the USA was halved. Nations represented among the editors of 2/e that were not represented in 1/e include Luxembourg, Greece, Finland, Japan, China, Ireland, Singapore, Spain, Russia, Austria, Israel, and the Netherlands. The presence of several Asian nations on this list is particularly gratifying. To be sure, the North Americans and Western Europeans still predominate, but they no longer monopolize the field.

Adding the International Board of Consulting Editors (see the following statement of Acknowledgments) increases the internationalism of the editorial team even further. Of the 45 members of that Board, only 12 (27%) are US social and behavioral scientists. Countries represented on that Board that are not otherwise part of the editorial team include three Central and South American nations (Venezuela, Argentina, Costa Rica), several Asian nations (the Philippines, Malaysia, South Korea, India), a few Western European nations (Norway, Denmark), two representatives from Central and Eastern Europe (Hungary, Croatia), two from the Middle East (Lebanon, Qatar), and one from South Africa. These editions bring to 35 the total number of countries with representation on the IESBS editorial team.

Much the same can be said of the 2/e authors, who are also more international than the 1/e authors had been. Smelser and Baltes noted in their Introduction that while authors from 51 nations were represented in the work,

58% of the authors were from North America and another 35% were from (mainly Western) Europe. "As to gender composition, 21% of the [1/e] authors were women." In 2/e, the proportion of women among the authors has increased slightly to approximately 25% and the percentage of North American authors has declined to fewer than half. Again, North America and Western Europe still contribute the larger share of the 2/e authors but the growing representation of social and behavioral science authors outside the West is both noteworthy and encouraging.

Another important point is that the international scope of the project is much more pronounced than editors' and authors' current affiliations would lead one to conclude. (This would have been equally true in 1/e as well.) Consider, for example, Michiru Nagatsu, author of our article 03053 on the history of behavioral economics. Dr Nagatsu was born in Japan and retains Japanese citizenship but was educated at Exeter and the London School of Economics and Political Science and wrote his IESBS 2/e article while on a postdoctoral fellowship in Finland. Or Guillermina Jasso, area editor for Area Three. Jasso was born in the USA, received her PhD from Johns Hopkins, and is on the faculty at New York University. By any standard, she would count as a US sociologist in our compilations. Yet her parents were Mexican of Basque, Spanish, Portuguese, and Dutch origins; Spanish is her native language; over the course of her distinguished career, she has published with coauthors from Germany, India, Israel, Mexico, the Netherlands, and Sweden; and she holds a permanent research fellowship at IZA, the Institute for the Study of Labor, in Bonn, Germany. Scoring her as 'USA' scarcely does justice to her biography or to the international perspective she brought to the editorial task.

What is true of author Nagatsu and editor Jasso is true in degrees of virtually the entire roster of IESBS participants. If one includes place of birth, citizenship, where educated, sites of research, visiting appointments, sites of fellowships, honorary professorships, invited lectures, and on through the list of highlights in a modern academic career, it is safe to say that every nook and cranny of the globe (save, possibly, Antarctica) is represented somewhere in the biographies of IESBS authors and editors. The true measure of internationalism, in short, is not so much where people come from or where they currently are, but rather the extent to which they bring a sensitivity and commitment to cultural and national differences into their work. Whether this was or was not realized in 2/e is for readers to decide.

Concluding Observations

Smelser and Baltes aspired in the first edition of this work to "assemble the whole range of knowledge – vast and complex as it is – of the social and behavioral sciences in one place." Since what does and does not qualify as 'social and behavioral science' is itself contested, it is not surprising that nearly every one of the market reviews commissioned by Elsevier to guide the development of the current edition noted content omissions in 1/e that reduced its usefulness and that needed to be addressed in a second edition. Critics can and no doubt will say the same about 2/e. I have already mentioned the nearly 800 articles that appeared on the 2/e Table of Contents at one time or another but that will not be found in the final product, either because agreeable authors could not be located or (less often) because agreeable authors never produced an acceptable article. And it is pretty easy to identify whole chunks of present-day social and behavioral science that are given short shrift, or no shrift at all, in this work – not because these chunks were judged to be unimportant but because limits of time, space, resources, and networks meant that some elements of the contemporary social science enterprise never came to our attention.

The social and behavioral sciences begin with what artificial intelligence guru Marvin Minsky once described as a "three pound computer made out of meat" – the human brain, which for all we know is the most complicated three-pound hunk of matter in the universe – and end with a thoroughly globalized culture and social structure that encompasses all aspects of our species' physical, biological, psychological, social, emotional, cultural, and spiritual lives. We are the most successful species ever to have inhabited the planet; we have colonized every inhabitable piece of dirt; our range extends everywhere; all the earth's resources lay at our command. To record all that has come to be known about human origins, evolution, language, culture, and social structure – everything we know about human emotions, identity, love, religion, family, economics, politics, domination, exploitation, and on through a very long list – would require orders of magnitude more volumes than the mere 26 volumes that comprise the present work.

We have come increasingly to the realization that what is social and human about our species is very intimately connected to our biological, genetic, and evolutionary inheritance. At the same time, the brain specifically and biological evolution more generally "cannot be viewed separately from the material, historical and

social circumstances that produce it" (Berntsen and Baker, 2015). As these authors put it, biology and culture are 'mutually constitutive.' Fifteen years ago, the editors of the first edition remarked on "ferment at the boundaries between the biological and the behavioral and social sciences." And while there are still important controversies, much of the ferment has yielded to cooperation as we are just now beginning to explore this endlessly complex web of interconnectedness between our biological and social selves. It is an easy and nearly inevitable conclusion, thus, that the third edition of the IESBS will contain a great deal more of the work being done at this intersection than 2/e was able to accommodate.

To conclude on a purely personal note, the 5 years I have spent working on this project produced many professional and personal gratifications, none quite so delicious as the certain knowledge that I would learn something new every single day. My work on 2/e exposed me to literature I never knew existed and to aspects of the social and behavioral sciences of which I was at best dimly aware. I can only hope that readers who come to these pages will find them as enriching as I have.

ACKNOWLEDGMENTS

A work of this scale is inevitably a communal enterprise involving many hundreds of editors, authors, reviewers, technical support people, colleagues, professional acquaintances, and friends who have provided input, advice, encouragement, and assistance over the past five years. Any listing is bound to be incomplete, so my apologies in advance to those who expected to be mentioned here but are not. Be assured that the slight is not intentional.

My negotiations with Elsevier about this project began early in 2010. By May of that year, I had committed to the project and have been working on it at varying levels of intensity ever since — often on weekends, during holidays, and whenever else I could snatch a useable chunk of time. So my first acknowledgment must be to my wife Chris for suffering through my five year obsession, always with understanding and affection, usually with good cheer. Chris is probably the only person in the world who is happier than I am that the project is now completed.

I must also acknowledge an enormous intellectual debt to the editors in chief of the first edition of the *International Encyclopedia of the Social and Behavioral Sciences*, Drs Neil Smelser and Paul Baltes (the latter now deceased). Dr Smelser was gracious enough to serve as Chair Emeritus of the project's International Board of Consulting Editors and to put himself at my disposal as, in his words, "a battle-scarred veteran." The basic intellectual structure of this work is adopted more or less wholesale from the Smelser—Baltes edition, with a few exceptions noted earlier in the *Introduction*. Without the original to serve as the starting point and blueprint, it is hard to imagine even embarking on such a task, much less bringing it to completion. Their edition was hailed as "the largest corpus of knowledge about the social and behavioral sciences in existence," which is to say that it formed an *extremely* solid foundation from which to build the work you now hold in your hands.

The first edition was organized into 39 sections overseen by a team of 53 section editors. The structure of the second edition is slightly different. It is divided up into 10 broad 'Areas,' each with an Area Editor overseeing the work of between four and eight Section Editors. In all, the second edition is thus comprised of the 10 Areas subdivided into 53 Sections; the 53 Sections were developed by a team of 76 Section Editors. So whereas Smelser and Baltes had 53 colleagues to help complete the work, I had 84 (two of the Area Editors also edited their own sections). On pages i-v in the front matter to this work one finds an Editorial Board list showing the Area Editors, Section Editors, Sections, names, and affiliations of the entire editorial team — a team whose dedication and effort in behalf of the project has vastly exceeded the rate of pay. A more helpful, productive, or delightful group of scholarly collaborators is difficult to imagine.

What readers see in the listed Editorial Structure of the work is the *final* editorial team as it existed when the work went into production. As would be expected in a project of this duration, there was considerable turnover within the team as the project developed and as death, competing demands, and general indifference all took their toll. I am grateful, nonetheless, to everyone who agreed, at least initially, to participate in the project, whether or not they were able to stay involved to the very end.

Susan Hanson (Geography) and Ulf Hannerz (Anthropology) are owed a special note of thanks because, of the 53 Section Editors involved in the first edition, these are the only two who agreed to reprise their roles in the second. (Both also wisely requested and received coeditors to carry part of the load.) Persuading people to serve who had no real idea what they were getting into was challenge enough, but these two suffered through 1/e and were willing to do it all over again for 2/e. And for that, I am especially grateful.

Many of the editors benefitted from the assistance of colleagues and graduate students at their various institutions. There was no mechanism built into the editorial process to keep systematic track of this

assistance and so the listing below is certain to be incomplete. But I can at least acknowledge those of whom I am aware who contributed time and intellectual energy to the effort: Liam Morton and Andrea Livingstone (Psychiatry); Jennifer O'Connor and Alana Dorris (Applied, Industrial and Organizational Psychology); Jen Hanis-Martin (Sexuality); David Budde, Annette Stimmer, Nikolas Ott, and Franziska Pfeifer (Institutions and Infrastructure of Social and Behavioral Sciences); Matthew LeDuc and Scott Freeman (Contemporary Cultural Concerns); and Simone Dudziak (Public Policy). To those named, my thanks. To those omitted, my apologies.

A special note of thanks to Dr Donald J. Barrett. Don was originally recruited to develop an entirely new section of the second edition on Gay, Lesbian, Bisexual, and Transsexual Studies, completed the section in short order, then e-mailed me to ask if there was anything further he could do to be helpful. Consequently, he took a major hand in developing the section on Biographies and was quite helpful with many other sections too. He appears in the Editorial Structure both as a Section Editor and as a Senior Editorial Associate to acknowledge his yeoman service to the entire enterprise. Also listed as a Senior Editorial Associate is my colleague Dr Amy M. Donley, who has been with the project since the very beginning and who, more than once, was all that stood between me and madness. I am proud to count them both as colleagues, collaborators, and friends.

I am also pleased to acknowledge Don Barrett, Andreas Hess, Harry Whitaker, John Berry, Barbara Miller, Scott Bentley, and Claire Byrne for their incisive and helpful commentary on previous drafts of the Acknowledgments and Editor's Introduction.

The project's International Board of Consulting Editors, chaired by Smelser and Dr Peter Marsden of Harvard University, was formed late in 2011 as a 'sounding board' to be used by the Area and Section Editors in searching for topics and authors and to help push for greater internationalism in our coverage. As it turned out, several members of this Board also stepped up to write entries in their areas of expertise. The composition of this Board and the affiliations of the consulting editors (as they were when the Board was first formed, not necessarily as they are today) are as follows: Neil J. Smelser, *University of California, USA*; Peter V. Marsden, *Harvard University, USA*; Ronald F. Abler, *International Geographical Union, USA*; John Bacon-Shone, *University of Hong Kong, China*; Roberto Briceño-León, *Universidad Central de Venezuela, Venezuela*; Roel Bosker, *Rijksuniversiteit Groningen, The Netherlands*; Michael Burawoy, *University of California, Berkeley, USA*; Nestor T. Castro, *University of the Philippines, Philippines*; Dalton Conley, *New York University, USA*; Freek Cronjé, *North West University, South Africa*; Scott Davies, *McMaster University, Canada*; Abdul Rahman Haji Embong, *Malaysian Social Science Association, Malaysia*; Joan-Maria Esteban, *Barcelona Graduate School of Economics, Spain*; Robert S. Feldman, *University of Massachusetts, USA*; Sari Hanafi, *American University of Beirut, Lebanon*; Gudmund Hernes, *Norwegian Business School, Norway*; Sheila Jasanoff, *Harvard University, USA*; Tim Jensen, *University of Southern Denmark, Denmark*; Colin Jones, *University of London, UK*; Nadezhda Lebedeva, *Higher School of Economics; and National Research University, Russia*; Miklós Lévay, *Eötvös Lorand University, Hungary*; Dinka Marinovic Jerolimov, *Institute for Social Research, Croatia*; Laurie M. Joyner, *Rollins College, USA*; Ferenc Kiefer, *Hungarian Academy of Sciences, Hungary*; Pan Suk Kim, *Yonsei University, South Korea*; Katsuya Kodama, *International Peace Research Association; and Mie University, Japan*; Allan Lavell, *Facultad Latinoamericana de Ciencias Sociales (FLACSO), Costa Rica*; Jake Lynch, *University of Sydney, Australia*; Cecilia Mabragana, *Consejo Nacional de Investigaciones Cientificas y Tecnicas (CONICET), Argentina*; William McBride, *Purdue University, USA*; Ishwar Modi, *University of Rajasthan, India*; Leonardo Morlino, *School of Government, Italy*; Melvin L. Oliver, *University of California, USA*; Angela M. O'Rand, *Duke University, USA*; Kenneth Prewitt, *Columbia University, USA*; Thilo Rehren, *University College London Qatar, Qatar*; Colette Sabatier, *Université Victor Segalen, France*; Philip Schofield, *University College, UK*; Rainer K. Silbereisen, *University of Jena, Germany*; Chamhuri bin Siwar, *National University of Malaysia, Malaysia*; Tom W. Smith, *World Association for Public Opinion Research, USA*; Catalina Smulovitz, *Universidad Torcuato Di Tella Miñones, Argentina*; Philip Spinhoven, *Leiden University, The Netherlands*; Sukhadeo Thorat, *Indian Council of Social Science Research, India*; Nigel Thrift, *University of Warwick, UK*; John R. Townshend, *University of Maryland, USA*; Gisèle Yasmeen, *Social Sciences and Humanities Research Council of Canada, Canada*.

Searching for an editorial team to represent every social science discipline and every region of the globe quickly exposed the deficiencies in my personal network, so I am indebted to a very large number of scholars around the world for calling names of prospects to my attention, allowing me to drop their names in the recruitment effort, or otherwise helping me find people with the expertise and commitment required for the job. In most cases, this is a list of people who were invited onto the editorial team in some capacity,

demurred, but made valuable suggestions about others to contact. In several cases, people are listed because they engaged me in intellectual discussions about the structure, format, and even advisability of this work, or simply replied to a cold-call e-mail in pleasant, kind, helpful, or informative ways. Again ignoring the risk of omission, my sincere personal thanks to those named below for their contributions large and small to the final product:

Doug Anderton, Juri Allik, George Armelagos, Susan Ayers, Amanda Baumle, Janeen Baxter, Jess ben-Habib, Joao Biehl, David Blanchflower, Hans-Peter Blossfeld, Jason Boardman, Dorret Boomsma, Roel Bosker, Henry Brady, Martin Bulmer, Craig Calhoun, Miguel Centeno, William Cockerham, Mark Nathan Cohen, Amelie Constant, Simon Cottle, Connie Citro, Eileen Crimmons, James Curran, Scott Davies, Donatella Della Porta, George Downs, Francis Dodoo, David Dozois, Sonja Drobnick, Jaap Dronkers, John Dryzek, Riley Dunlap, Lauren Edelman, David Elesh, Paula England, Nancy Eisenberg, Geoffrey Evans, Miriam Faust, Robert Feenstra, Marcus Feldman, Stanley Feldman, Ronald Fischer, James Fowler, Jeremy Freese, Angela D. Friederici, Michael Frumpkin, Masahisa Fujita, Nicole M. Gage, Nancy Gallini, Rosemary Gartner, Morton Ann Gernsbacher, Robert Goodin, John Grattan, Lance Gravlee, David Greenberg, Wendy Griswold, Melanie Guldi, Monica Das Gupta, Peter Hatemi, Robert Haveman, Karen Heimer, John Hibbing, Sarah Blaffer Hrdy, Sheila Jasanoff, Kelly Kadera, Cigdem Kagitcibasi, David Kavanaugh, Roger Keil, Byungkook Kim, Rob Kitchin, Jack Knight, Lyle Konigsberg, Candace Kruttschnitt, Helen Ladd, Phillip Lane, Graeme Lang, Janet Lauritsen, Ashley Leeds, Evelyn Lehrer, Richard Lerner, David Lewis, Tim Liao, Tom Linneman, Norman Long, Karen Lyons, Ruth Mace, Gary Marks, Herbert Marsh, Karl-Ulrich Mayer, Lorraine Mazerolle, Rose McDermott, Susan Michie, Harry Minas, Peter Miller, S. Phillip Morgan, Victor Nee, Vin-Kim Nguyen, Paul Nieuwbeerta, Helga Nowotny, Howard Nusbaum, Claus Offe, Thomas Ollendick, Joan Orme, Dennis O'Rourke, Michael Overington, Catherine Panter-Brick, Susan Parnell, Deborah M. Pearsall, Gerard Pfann, Jon Pierre, Mike Ping, Jennifer Platt, Ken Prewitt, Cathy Price, Jill Quadnagno, Charles Ragin, Thilo Rehren, Ben Rosamond, Bo Rothstein, Beth Rubin, Heinrich Sauer, Peer Scheepers, Ralf Schwarzer, Moshe Semyonov, Michael Shanahan, Sara Shostak, Alan Sica, Rainer K. Silbereisen, Beth Simmons, Catalina Smulovitz, Michael Sobel, Diane Stone, Jill Stephenson, Rafe Stolzenberg, Miron Straf, Richard Swedberg, Alan C. Swedlund, Sidney Tarrow, Jacques-Francoise Thisse, Stefan Timmermans, Florencia Torche, Erik Tsang, Judy Treas, Billie Turner, Cees van der Eijk, Paul van Lange, James Vaupel, Karin Wahl-Jorgensen, Mitchell G. Weiss, Neil Whitehead, Pamela Wilcox, Bjorn Wittrock, Cornelia Woll, Gisele Yasmeen, and Barbie Zelizer.

Gratitude is owed as well to the many colleagues at Elsevier who contributed to the production of this volume. My first debt is to Claire Byrne, the project's Content Project Manager and the head of the Major Reference Works (MRW) team that managed the day-to-day *Sturm und Drang* of the project: aggrieved, confused, or delinquent authors, missed deadlines, testy and intransigent editors, and the often-maddening work style of the Editor in Chief. I am sure there were days when Claire wanted to tear her hair out, but to external appearances, she was an island of calm in a sea of turmoil. She was also exceptionally good at her job.

Claire's MRW team comprised Richard Berryman, Will Bowden-Green, Esmond Collins, Mark Harper, Sam Mahfoudh, Mike Nicholls, Gemma Tomalin, Joanne Williams, and Marise Willis. No matter what issue or problem I faced, one of these fine, capable people was always available to step up with a solution, invariably offered in a spirit of cooperation and good cheer. They have been to IESBS 2/e what tech support is to the modern computerized office. Getting this work completed without their help is inconceivable.

Thanks also to the succession of Elsevier's Acquisitions Editors who managed the finances and internal politics of the project: to Scott Bentley, whose gentle suasions pulled me into the project in the beginning; to Karen Maloney and Peter Labella who ran the show in the middle period; and to Lisa Tickner who was in charge at the very end. These are the people on the front line in the endless war between the publisher, who wants things done now and at minimal expense, and the Editor in Chief, who was always asking for more time and more money. The many dozens of amicable compromises necessary to bring the project to completion were all ably negotiated by Scott, Karen, Peter, and Lisa, and for that, I am grateful indeed.

The University of Central Florida and its Department of Sociology have provided a congenial home for the project. My thanks in particular to Dean Michael Johnson; to the current and former chairs of my department, Jana L. Jasinski and Libby Mustaine; to my faculty colleagues Liz Grauerholz, Phillip 'Hutch' Pollock, Bruce Wilson, Melanie Guldi, Stacy Barber, Tosha Dupras, and John Schultz; and to current and former graduate students Thomas Hall, Sara Strickhouser, Betsy Swart, Jordana Navarro, Marie Gualtieri, Shannon Simone, and Shannon Frey.

And most of all, my sincere thanks to the many thousands of authors whose work this is. When comparing the quality of the work contained within these pages to the authors' honoraria, it is obvious that IESBS 2/e is an act of collective charity by our authors to the disciplines they represent. It is my pleasure to thank our authors on behalf of the global social science community.

GUIDE TO USING THE ENCYCLOPEDIA

Structure of the Encyclopedia

The material in the Encyclopedia is arranged as a series of articles in alphabetical order.

There are four features to help you easily find the topic you are interested in an alphabetical contents list, cross-references to other relevant articles within each article, subject classification index, and a full subject index.

1. Alphabetical Contents List

The alphabetical contents list, which appears at the front of each volume, lists the articles in the order that they appear in that volume of the Encyclopedia. It includes both the volume number and the page number of each article.

2. Cross-references

All of the articles in the Encyclopedia have been cross-referenced. The cross-references, which appear at the end of an article as a See also list, serve three different functions:

a. To draw the reader's attention to related materials in other articles.
b. To indicate material that broadens and extends the scope of the article.
c. To indicate material that covers a topic in more depth.

3. Subject Classification Index

This index appears in Volume 26 and groups articles under subject headings that reflect the broad themes of Social and Behavioral Sciences. This index is useful for making quick connections between articles and locating the relevant article for a topic that is covered in more than one article. Under some section headings, you will find subheadings, if it is appropriate for the articles in a subject area to be grouped into more specific subareas.

4. Contributors

At the start of each volume, there is list of the authors who contributed to that volume.

5. Index

The index appears in Volume 26. The index includes page numbers for quick reference to the information you are looking for. The index articles differentiate between references to whole article, a part of an article, and a table or figure.

Abstract

This article considers genocide as a general type of political violence and violent conflict, together with its relationships to the larger fields of political and armed conflict, especially war. The article deals first with the conceptual delimitation of these terms and then with the analytical issues involved in their relationships in different historical periods up to and including the present.

Introduction

Genocide is increasingly considered as a major phenomenon of modern world history, and has become the subject of the growing interdisciplinary field of genocide studies. This field generally studies 'genocides,' understood as discrete episodes of group destruction, generally in a comparative vein, so that the name of the field is often qualified as comparative genocide studies. However, from the first discussion of the topic in the closing stages of the World War II, genocide has been seen as having particularly close connections with war. Most major genocides have either taken place during wars (for example, the Armenian Genocide and the Holocaust during the World Wars I and II respectively, and the Rwandan Genocide during the civil war in that country), or as a consequence of wars (for example, the Cambodian Genocide at the conclusion of the wars in Indo-China). Almost all genocides involve the use of military power against civilians, and many are committed by militarized regimes or armed organizations of one kind or another. Indeed, genocide can even be seen as a particular form of war, distinguished by the fact that armed force is targeted not at armed opponents, but at civilian social groups. This apparently close connection raises problems, however, for the idea that genocide can be a distinct field of study, and equally for the idea that we can study war without problematizing genocide. This article explores the roots of this connection and the range of issues for the study of organized violence that arise from it.

The Origins of the Genocide Idea in War

The concept of genocide was first developed in the early 1940s by the lawyer, historian, and campaigner Raphael Lemkin as a general sociological and legal category to describe targeted destruction of social groups. The word first appeared in print in Lemkin's critique of *Axis Rule in Occupied Europe* (1944), in which he analyzed a 'Nazi genocide' against the many national groups of German-occupied Europe. Lemkin stressed the multimethod attack on populations (he did not confine genocide to physical violence but included economic, legal, cultural, and many other forms of coercion too), and the general character of national destruction across the occupied countries (he did not restrict genocide to the destruction of the Jews, even though he was well aware of the extreme murderousness directed at them in particular). Lemkin recognized that many of the acts of genocide were already covered by existing laws, but he argued for the need to define a general crime of group destruction.

The original publication of the idea in a book about Nazi occupation policies underlined the strong connections between Lemkin's conception of genocide and the context of war. The earliest uses of the idea – for example, when it was cited in the Nuremberg trials of Nazi war criminals in 1946 – emphasized this context. Nevertheless, Lemkin aimed to establish genocide as an international crime, whether it was committed in war or in peace, and this was reflected in the Convention on the Prevention and Punishment of the Crime of Genocide, adopted by the United Nations in 1948. Subsequently, as the Cold War developed, the idea was rarely invoked in legal settings (the UN did not establish the International Criminal Court, envisaged when the Convention was adopted, until the twenty-first century). However, it gained wide political and cultural currency, and was increasingly invoked whenever mass violations of human rights were committed.

Owing to the origins of the idea in the World Wars of the twentieth century, the type of war–genocide connection that was originally remarked was the linkage with total war, in which states targeted each others' populations as a means of defeating the enemy state. This type of war – degenerated because of the centrality of direct civilian targeting – culminated in the atomic bombing of Hiroshima and Nagasaki, and has sometimes been seen as genocidal in itself. However, it can be argued that the USA, like Britain in its bombing of Germany, did not see the opposing population as an enemy to be destroyed in themselves, and therefore ceased attacking them when their states surrendered. Nazi Germany, on the other hand, clearly regarded Slav as well as Jewish populations as enemies, the destruction of whose societies was a goal of the war, alongside the destruction of enemy states.

Thus in the Nazi case, it is difficult to distinguish the conventional wars that the state was fighting against the USSR and the Western Allies from their antipopulation policies. At the macro level of state policy, Germany's war, at least in Eastern Europe, was generally a racial war to enslave inferior peoples, hence one might say a genocidal war. At the meso level of strategic implementation, while the regime created specialized agencies like the paramilitary Schutzstaffel (SS) that were particularly charged with pursuing genocidal goals, the

Reichswehr (regular army) was also involved in the practice of genocide. During the invasions of Poland, the Soviet Union, Yugoslavia, and other countries, this went hand in hand with the regular campaign on the front, as well as being pursued after conquest in the occupied territories. At the micro level of implementation, German soldiers and civilian personnel together with local auxiliaries, including sometimes local civilians, had both 'war' and 'genocide' ideas in their heads as they dealt with local populations.

The understanding of these linkages has been blocked because the Nazi genocide has subsequently been misunderstood solely or mainly as a campaign against the Jews, and the latter has been misunderstood solely as a campaign of industrial extermination in death camps. However, until 1942, the Germans had been responsible for killing more Slav than Jewish civilians; and the campaigns against the Jews, which began with discrimination and pogroms in Germany itself before the war, had proceeded after the invasion of Poland through phases of expulsion and ghettoization, combined with violence against Slavs, before culminating in industrial gassing after the invasion of the USSR. Anti-Jewish policies were a distinct component of Nazi practice, but their implementation was combined with antipopulation policies against Slavs, Roma, and others, all of which conditioned each other in, and were conditioned by, the context of war.

It can be seen from this classic example that the connections of war and genocide can be complex: the same German actors were fighting a relatively conventional – albeit total and degenerate – war against the Western Allies and a genocidal war against the Soviet Union, while pursuing an array of specific genocidal policies against Jews, Slavs, and others. Where did war end and genocide begin? How far were the connections internal, because the war aims were themselves genocidal, or external and causal, in that war conditioned genocide and vice versa?

Genocide and Genocidal Violence

These issues only become more difficult when we consider a wider range of cases of both phenomena. The Nazi genocide, as Lemkin called it, was manifestly a large complex of policies and practices emanating from a large imperial state, centrally directed by a totalitarian regime. Although historians now emphasize the roles that local Nazi leaders, army commanders, allied states, auxiliaries, and even non-German civilians played in producing genocide, there is little doubt that the main drivers came from the top, indeed from a single leader, Adolf Hitler. This was mostly true of other European genocide in the era of total war, from the Ottoman killing of the Armenians to the Soviet 'terror-famine' and deportations of 'treacherous' nationalities and, after the World War II, the great mass deaths are produced by Chinese and Cambodian Communism.

However, not all genocide can be considered top-down in this way. Colonial genocide, during and after the European conquests of parts of the Americas, Australasia, Asia, and Africa, was often carried out by settlers, even against the opposition of the distant imperial state and its local representatives. Sometimes settlers' local authorities, and later the independent governments that colonists were able to be established, were the centers of genocidal policies against indigenous peoples. Often, however, it was local militias or simply ad hoc groups of settlers who expelled, killed, and raped them. These perpetrators were not fighting large-scale wars, but often short-lived local campaigns, or isolated skirmishes. They did not necessarily develop complex, formalized policies but improvised genocidal goals and practices as they saw fit in changing local circumstances. Often they did not carry out 'genocides' in the sense of complex episodes of large-scale dispossession and murder, but localized genocidal violence.

The literature uses the term 'genocidal massacre' (introduced by Kuper, 1981: 32) to describe more limited killing episodes, and by analogy we can talk of limited genocidal expulsions, genocidal rapes, etc. I use the general term 'genocidal violence' to refer to localized and limited acts of genocide, by whichever violent method. It is necessary to comment on the inclusion of expulsions and other acts of forced population removal – deportations, terrorized flight, etc. – within the framework of genocidal violence. These are sometimes considered 'ethnic cleansing' rather than genocide, the term being adapted from language long used in the Balkans and which entered international and academic discourse during the 1990s Yugoslav wars. 'Cleansing' terminology is manifestly euphemistic, and since forced removal of populations has long been a prime means of destroying particular societies and cultures, the phenomenon belongs to genocide. However, the terminology is highly politicized, with specific mention of forced removal omitted from the UN Convention because UN states carried it out, and 'ethnic cleansing' often preferred by statesmen because it does not imply the same legal obligations as 'genocide.' Here forced removal is considered a method of genocide and one form of genocidal violence.

Distinguishing and Relating Genocide to Other Types of Violence in War

This terminology is useful in analyzing not only colonial but also more recent genocide. Historically, highly centralized, statist genocide is the exception, and since the 1940s, genocide has appeared in a wide range of contexts but often with more limited scope and decentralized, less state-centric direction. During the Cold War period, genocide was a dimension of armed conflicts between Communists and anti-Communist forces, wars of decolonization, secessionist wars, and post-colonial civil wars. Since the end of the Cold War, it has continued to be a feature of secessionist and national power conflicts, and increasingly of electoral struggles, particularly in democratizing countries, often influenced by the UN and Western interventions and global media coverage. In short, genocide and genocidal violence are phenomena of a wide range of political and armed conflicts in the twenty-first century.

However, the complex tasks of distinguishing and analyzing the relationships of genocide and war have been affected by changes both in conflict itself and in the discourses surrounding it. The very use of the term 'conflict' reflects these changes. Whereas the twentieth century was dominated by large, long, often formally declared interstate wars, in the twenty-first (so far), wars are often relatively small, short, only

rarely interstate in a straightforward sense, and hardly ever declared. Although 'small wars' have always been more numerous than major interstate wars, there has been a marked trend of decline in the latter. There is a widespread consensus that war has changed its appearances: the majority of contemporary wars are civil wars, albeit usually internationalized. Moreover, while any use of organized armed (military) violence against a similarly armed enemy can be considered an act of war, and any conflict between organized armed opponents belongs to the realm of war, analysts have often been hesitant to apply the label 'war' to relatively small, short, localized conflicts, especially where the protagonists are mainly not recognized state actors. Hence there is a resort to 'armed conflict' as a description of the field of organized violence previously described as 'war,' and a frequent use of 'political violence' to recognize the overlap of war with other types of violent action and conflict. Thus problems in identifying contemporary trends reflect mutations in the phenomenology and perceptions of violence. According to Mary Kaldor (1999), we are in an era of 'new wars' combining civil and interstate dimensions, paramilitarism, identity politics, and ethnic targeting with parasitic, globalized war economies. Her account emphasizes 'ethnic cleansing' as a novel feature, although this begs questions about historical patterns of 'cleansing' and genocide in what she calls 'old' war. Yet, while the depth of this novelty is often disputed, the idea that the appearance of conflict has changed is widely shared.

The recognition of genocide has naturally been affected by these changing perceptions of war. Even the best recognized 'genocides' took place in contexts of general war and were often seen at the time as excesses of war. Their analytical recognition depended on simultaneously distinguishing genocide from and understanding its linkages to war, as well as overcoming denialist ideas representing genocidal violence as 'only' war. In today's wars, genocide's distinction from the wars and political conflicts of which it is a part may be less obvious. In considering these conflicts as a whole, moreover, it may be appropriate to use 'war,' 'armed conflict,' or 'political conflict' rather than 'genocide' as the dominant frame, and to conceptualize genocidal violence as a component of such conflicts.

The problem of recognizing genocidal elements in contemporary conflicts is exacerbated by the fact that genocide is often perceived as linked to the 'totalitarian/radical party' type of regime, the prevalence of which has declined together with twentieth-century types of extreme ideology. Actors' commitments to clear ideological frames, through which relatively coherent antigroup policies are formulated, have become less common; antigroup drives seem to reflect more contingent political interests. At the same time, the 'sacred evil' quality of the Holocaust has increasingly been extended to genocide in general. Together with the beginnings of international enforcement of anti-genocide law and policy, this has increased the stakes in using the term. The term 'genocide' has become an even more crucial ideological prize, claimed by representatives of victim groups to elevate their victim experience to the highest level, and used in the new activism. For the opposite reason, states, interstate organizations, and NGOs mostly avoid the terminology because of its political and legal baggage. Academic analysts of antipopulation violence, armed conflict, and war have often followed suit, inventing new terminologies to describe violence that could be considered within the genocide frame. I have already commented on the adoption of the euphemism 'ethnic cleansing'; another widely used euphemism is 'humanitarian crisis,' a term as applicable to natural disasters as to the results of targeted violence against civilians, which serves to create vagueness about the latter.

There have also been more focused attempts to conceptualize violence against civilians in twenty-first century conflict. The Uppsala Conflict Data Program (2009) proposes the concept of 'one-sided violence,' defined as "[t]he use of armed force by the government of a state or by a formally organized group against civilians which results in at least 25 deaths in a year." The low quantitative criterion (matching the Uppsala criterion for 'armed conflict') usefully recognizes that such force can be used on a much smaller scale than that recognized by the widely used older 1000-battle-death criterion for a 'war.' Ekaterina Stepanova (2009: 39–40) explains the idea: "[o]ne-sided violence is not armed conflict as such, as it directly and intentionally targets civilians who cannot defend themselves with arms. It is also distinct from battle-related violence that incidentally harms civilians, for example when civilians are caught in crossfire between combatants." In "contrast to indiscriminate violence, one-sided violence is a matter of conscious political and strategic choice and not a technologically inseparable part of modern warfare."

By implication, 'one-sided violence' is selective and political; but since it includes 'massacres, arbitrary killings, and terrorist attacks,' it covers violence with a range of objectives. Yet, this Uppsala idea echoes influential definitions of genocide: the widely cited sociological authorities, Frank Chalk and Kurt Jonahsson (1991: 23) actually use the term 'one-sided mass killing' in their definition. Like genocide, 'one-sided violence' captures the crucial distinction of combatant–noncombatant from combatant–combatant violence. Indeed, Roberta Cohen and Francis Deng (2009: 20) confirm that the Uppsala terminology was adopted as much for reasons of political context as of intellectual coherence, describing 'one-sided violence' as "a UCDP term that moves away from the highly emotive words 'terrorism' and 'genocide'." However, the genocide theorists who emphasize one-sidedness are also those who narrow the modalities of genocide to mass murder, and similarly Uppsala *defines* violence in terms of killings, even if it recognizes mass population displacement, for example, as increasingly "a central and direct goal of armed violence, rather than a side effect" (Stepanova, 2009: 42) and a 'devastating transformation' of peoples' lives (Walter Kälin, quoted by Cohen and Deng, 2009: 16).

Extermination and Control

More theoretically conceived work in social science also tends to write genocide out of armed conflict, often by simply not referring to it. Even where genocide is recognized conceptually, it tends to be marginalized analytically. For example, in Stathis Kalyvas' influential *The Logic of Violence in Civil War*, whose "focus is on violence committed intentionally against noncombatants" (Kalyvas, 2006: 5), genocide is mentioned only briefly. Kalyvas recognizes, as I do, that actual civil wars

comprise different types of violence, and in distinguishing between different types, he argues that violence "can be used to *exterminate* a group or to *control* it" (2006: 29, emphasis added), and focuses on the latter type, 'also known as coercive violence.' In particular, Kalyvas concentrates on a particular type of violence, 'civil war violence,' which he explains as a strategically rational form based on the need of parties to civil wars to control populations. Although he too restricts his attention to homicidal violence, he claims that his theory also does well for "violence that stops short of homicide (e.g., arrest, torture, displacement)" (Kalyvas, 2006: 7), and recognizes that "[a]nalytically akin to physical destruction is mass deportation, sometimes referred to as 'ethnic cleansing'" (Kalyvas, 2006: 26). This analytical kinship lies, presumably, in the fact that forced population removal (of which direct deportation is only one method) is also a means of 'exterminating' a group, in the sense of destroying its physical, social, and cultural presence within its historic territory.

More formally, Kalyvas (2006: 30, Table 1.1) also presents a typology of mass political violence, differentiated by whether or not a political actor 'intends to govern the population targeted.' He sees 'state terror' and 'civil war violence' as forms of violence reflecting the intention to govern, and 'genocide and mass deportation' and 'reciprocal extermination' as forms that reflect the lack of this intention. Genocide is also defined as 'unilateral': this captures the defining one-sidedness of the relationship between perpetrator center and target group, but seems an insufficient characterization since genocide may be practiced by both sides in a conflict. (Presumably, this is what Kalyvas indicates by 'reciprocal extermination,' but this indicates, in my view, a different type of conflict rather than of violence.)

The two ways of distinguishing violence that Kalyvas uses, 'control/extermination' and 'intention to govern/not' seem similar (he apparently uses them interchangeably) but they should be separated. The intention to govern or not is a more precise formulation of the criterion for genocide: the point when a collective actor enters into the realm of removing, exterminating, or destroying a given population under its control, it abandons any intention of governing it. Control, on the other hand, is a more overriding concern that may be a rationale for either governance or extermination, and is a feature of both governing and exterminating processes. Thus 'intention to govern' helps *define* the difference between nondestructive coercion and genocide; the logic of 'control' helps *explain* the choice between the two.

Kalyvas regards 'civil war violence' as a specific type of coercive rather than exterminatory violence, explicable by the logic of control. What he fails to explain is why violence goes beyond coercion toward extermination: the escalation of violence from one type to another. As Laia Balcells (2010) suggests, discussing Franco's killing of Spanish Republicans after the end of the civil war, exterminatory violence may be explained by the same logic of control that is seen in war violence. Yet Kalyvas, while distinguishing 'civil war violence' as a particular type from civil war as such, tends to assimilate most actual violence in civil wars to this type, so occluding the question of exterminatory or genocidal violence. Kalyvas and Nicholas Sambanis' analysis of Bosnia (2007) examines Serbian 'ethnic cleansing' without reference to its exterminatory meaning for Bosniak, Croat, and plural communities, apparently because they explain it as a function of population control in conquered territory. But this is to confuse the question of 'government/not' with the question of dynamics of control.

The overriding reason why we cannot satisfactorily distinguish 'control' from 'extermination' is that *control is an essential aspect of extermination*. Questions of control are apparent at every stage in the movement to and practice of genocidal violence. Movement toward deportation may be, as Kalyvas and Sambanis suggest it was in Bosnia, a function of the failure of more limited coercion to control a population. But deportation does not necessarily end dilemmas of control: a population needs to be controlled during deportation, and a deported population usually still needs to be controlled where it is deported to. If the deport-to location is within the direct control of the deporters, deportation simply gives them new dilemmas of direct control, as for example, for the Nazis with Jews in Polish ghettos and the Stalinist regime with the remnants of deported minorities in their regions of exile. If the deport-to location is outside the deporters' control, different issues of control may still arise: Israel managed to remove most Palestinian Arabs from its territory in 1948, but has since spent over six decades attempting to control the responses of the resulting refugee populations. Moreover, since deportation is rarely total, removal of the majority of a population will usually be combined with issues of the control of the remaining minority, as Israel has also found.

Fully murderous policies certainly involve additional issues, but still include questions of control. To starve or kill on any scale requires prior control over the target population and control during destruction processes. Moreover, it is important to *represent* murderous policies as policies of control. For example, deportation may be presented as relocation for work, even where it is taking people to death, since target populations and third parties acquiesce more willingly in policies that they perceive as for control rather than for destruction. Mass murder, moreover, is usually combined with less destructive measures of control, because the killing of some is often designed as a means of controlling larger populations. For example, Feierstein (2010) argues that the Argentinian dictatorship's 'disappearance' of leftists in the 1980s was a means of reordering the whole national society.

Moreover, as Kalyvas (2006: 26) notes, "the methods used to achieve compliance and physical destruction may be similar," even if the objectives differ. To operationalize the distinction (govern or destroy) we therefore need to infer perpetrators' objectives from the context in which violence occurs. In the case of victims who have surrendered – whether originally combatants or not – it should be relatively simple to determine genocide. The same should be true of civilians murdered or expelled *after* armed conflict has concluded, and of course *outside* the context of armed conflict. In the case of those killed or expelled *during* civil war, however, the distinction will be less straightforward, requiring detailed knowledge of the relationships between the targets of violence and the armed conflict. Like the distinction between victims of 'civil war violence' and of 'collateral damage' from intercombatant violence, it is easier to outline in principle than to apply conclusively in practice. Actors may *combine* these types of

objectives: by having partially destructive and partially governing objectives toward the same population; by using destructive methods against one section of a population in order to reinforce government of a larger population; and of course by having governing objectives at one point in time and destructive objectives at another. Mann (2005: 6–7) notes that escalation toward more destructive ends is a normal feature of genocide: but *de-escalation* is also normal, in the sense that governance may be reasserted once a certain level of destruction has been accomplished. And of course, among the 'members' of a collective actor which has a governing policy, elements or individuals may pursue destructive policies – or vice versa.

All these elements of indeterminacy, arising from common issues of control in both governance and destruction, may complicate the ascription of *either* destructive *or* governing objectives to a given actor in a given situation. When control is to be achieved through selective violence, any perception of a distinct section of the population as an 'enemy' in a fundamental sense (whether 'ethnic,' 'political,' or other) will offer a rationale to extend civil war violence to genocidal violence. These questions arise, moreover, on the interfaces between all three levels of civil war that Kalyvas (2006) specifies: macro, meso, and micro. Introducing the genocide question means reproblematizing the macro level, because genocidal drives often crystallize mainly at that level. However, it does not necessarily mean a macro-down approach. Research on the Holocaust has emphasized the interconnections between levels in both directions, for example, how Nazi officials managing conquered populations in different jurisdictions 'worked to' Hitler and the central leadership, evolving 'solutions' to racial 'problems' which influenced the regime's overall policies. Gerlach's (2010) work on 'extremely violent societies' shows how central militaries and local movements have interacted to produce mass killing, for example, in Indonesia in 1965 and in Bangladesh in 1971. Toal and Dahlmann (2011) show how local political elites, controlling municipalities, were central to mass deportation and the consolidation of its results in Bosnia. Historical work, for example, on 'genocidal moments' in settler colonization in Australia and on the local genocide of Jews by Polish civilians in Jedwabne, also suggests that genocide may arise at the micro level.

Conclusions

Although the connections between genocide and war are as old as the idea of genocide, the issues raised have been shown to be particularly relevant in the twenty-first century context, which is widely recognized to involve simultaneous shifts in patterns of armed conflict and of antipopulation violence. The relationship is a core analytical challenge for social scientists in making sense of these phenomena, closely linked to the shared core insight that actual 'conflicts' or 'wars' *combine* what should be understood as different *types* of violence. Theoretically, distinct types of violence are not to be equated with different *methods*. Killing, for example, even of civilians, can be a function of war or of genocide, and indeed of different subtypes of violence within 'war,' as suggested by the distinction of 'civil war violence' from 'collateral damage,' as well as the difference between genocidal and military killing. The typology of violence reflects, rather, understandings of the different purposes of violence, which is why the typology has a potential explanatory significance.

It is important to emphasize, too, that analytical clarity on these issues enables social science to contribute to clearer public debate on anti-civilian violence in armed conflict. A clear distinction of genocide from war, combined with an understanding of its relationships to war, can help to cut through the self-serving obfuscations that are practiced on all sides in violent conflicts. While would-be spokespeople for victims will invariably claim all violence against particular groups of civilians as 'genocide,' spokespeople for perpetrators and often for third-party states and international organizations will typically represent genocidal violence as 'only' war, thus using the idea of war to deny genocide. From both sides of such arguments, the idea is presented that 'war' and 'genocide' are exclusive terms. Social science can show their complex interdependence and hybridity and thus contribute to more careful discussion of the related public issues.

Genocide, Historical Aspects of

Gunnar Heinsohn, Raphael Lemkin Institute for Comparative Genocide Research, University of Bremen, Bremen, Germany

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Mass atrocities – that were not defined as genocide before 1948 or as crimes of war before 1899 – are followed through the ages from tribal communities to modern nation-states with a special focus on ecological, demographical, and ideological factors behind major annihilations.

Initiatives to criminalize genocide are exemplified from first steps in ancient Hebrew law via similar approaches after the atrocities in sixteenth-century European colonies to the international conventions passed after the Holocaust, and the most recent efforts like the *Responsibility to Protect* (*RtoP*) initiative of 2005. The probability for contemporary and future perpetrations is illuminated by the youth bulge concept that helps to develop an index for mega-killing potential.

The Term Genocide

On 9 December 1948, the United Nations *Convention on the Prevention and Punishment of the Crime of Genocide* was adopted unanimously (by a vote of 55:0:0). By 2012, 140 nations had ratified or acceded to the treaty. The text of the Convention was mostly written by a Polish lawyer and Holocaust refugee, Raphael Lemkin (1900–59; Szawłowski, 2005) who, in 1933, had already proposed a measure against the 'crime of barbarity' to the *Legal Council of the League of Nations* in Madrid based on the Ottoman extermination of Armenians after 1915, and the Simele massacre of 1933 in which the Army of Iraq had slaughtered Christian Assyrians. In his 1944 study *Axis Rule in Occupied Europe*, Lemkin coined the term 'genocide' (from Greek *genos* = tribe, and Latin *caedere* = kill). In the Convention's article II

> genocide means any of the following acts committed with intent to destroy, in whole or in part, a national, ethnical, racial or religious group, as such: a. Killing members of the group; b. Causing serious bodily or mental harm to members of the group; c. deliberately inflicting on the group conditions of life calculated to bring about its physical destruction in whole or in part; d. Imposing measures intended to prevent births within the group; e. Forcibly transferring children of the group to another group.

The crimes mentioned in paragraphs a–e are generalizations of practices employed by Hitler's Germany after 1 September 1939 (beginning of the World War II) mostly against Jews and Slavs. Because 'politicide' – the murder of any person or people because of their politics or for political purposes – as well as 'ideological genocide' – the murder of any person or people because of their ideology, theory, or knowledge – were excluded from the UN Genocide Convention, scholars later broadened the concept. Rudolph Rummel's 'democide' may be considered as the most comprehensive term. It is the murder of any person or people by a political movement or a government, including genocide, politicide, and mass murder (Rummel, 1994: p. 39). Genocide and democide are used side by side with the term 'crimes against humanity' coined on 24 May 1915 by France, Great Britain, Russia, and the United states on behalf of the Ottoman Armenians as "new crimes of Turkey against humanity and civilization." The term 'crimes against mankind,' created on 12 October 1942, in London ('Declaration of St. James') to denounce the Holocaust, is also still in use. Less known is the French term "populicide" coined by Gracchus Babeuf (1760–97) as a shorthand for his 'système de dépopulation,' which was carried out – during the French Revolution – in the Vendée (1793/94) by killing its entire royalist peasantry of some 120 000 (Babeuf, 1795). A more recent formula used by the *International Criminal Court* defines genocide as "the deliberate and systematic destruction, in whole or in part, of an ethnic, racial, religious, or national group" (Funk, 2010: p. 9).

The Study of Genocide

History of the Discipline

The discipline of comparative genocide research was established by Lemkin, who by 1959 had drafted three volumes on the *History of Genocide*. Several publishing houses turned him down. The manuscripts are kept (under "*Series III: History of Genocide*") by the *American Jewish Historical Society: Center for Jewish History* in New York (Elder, 2012).

The 1967–70 massacres of Ibos, who were trying to secede from Nigeria, with an estimated death toll of 500 000, triggered a worldwide interest in genocide (Gould, 2012). In 1970, Yvan van Garsse published *A Bibliography of Genocide Crimes against Humanity and War Crimes*. The genocide, in 1971, of up to 1.5 million citizens of secessionist East Pakistan (today's Bangladesh) by West Pakistan's army and militias, also drew attention to the subject (Mascarenhas, 1986; Linton, 2010). Both mega-killings had worldwide television coverage. However, it was not understood that both Nigeria (20–60 million inhabitants from 1940 to 1970) and Pakistan (60–135 million) were going through massive 'youth bulges.' Youth bulges are defined by at least 30% of the male population in the age bracket 15–29 years, i.e., there are three or more sons per father desperate for positions in society.

The Twentieth Century Book of the Dead by Gil Elliot (1972) became the first major monograph devoted to comparative genocide research. In 1976, sociology entered the field with Vahakn Dadrian's "A Typology of Genocide." Irving Louis Horowitz's *Genocide: State Power and Mass Murder* followed a year later. In 1981, Leo Kuper found a major academic publisher, Yale University Press, with *Genocide: Its Political Use in the Twentieth Century*. More systematically and historically minded works followed in 1990 with Helen Fein's *Genocide: A Sociological Perspective* as well as Frank Chalk's and Kurt Jonassohn's *The History and Sociology of Genocide*.

The first – one person – institute devoted to this subject – *Institute on the Holocaust and Genocide* – was founded in 1979 by Israel W. Charny in Jerusalem. Helen Fein followed, 1982 in New York, with the *Institute for the Study of Genocide*. Next were Frank Chalk and Kurt Jonassohn with the Canadian *Institute for Genocide and Human Rights Studies* (Montreal, Concordia University). Late starters were Australia with the *Centre for Comparative Genocide Studies* (Macquarie University) initiated in 1993 by Colin Tatz as well as Europe with the *Raphael-Lemkin-Institut für Xenophobie- und Genozidforschung* (University of Bremen/Germany) founded in the same year by Gunnar Heinsohn, Klaus von Muenchhausen, and Léon Poliakov. An *International Association of Genocide Scholars* (http://genocidescholars.wsg.net) was established in 1994. In 2005 followed the *International Network of Genocide Scholars* with more than 300 members in 2012 (http://www.inogs.com).

The first encyclopedia of genocide was published in Germany (Heinsohn, 1998) after Rummel's seminal *Statistics of Democide* (1997). A similar endeavor in English followed 2 years later (Charny, 2000). Meanwhile, there are quite a few general works available (Valentino, 2004; Levene, 2005; Kiernan, 2007; Moses, 2008; Goldhagen, 2009; Jones, 2010; Pinker, 2011: Chapters 1–7; Staub, 2011). *Necrometrics* by Matthew White keeps death tolls up to date (http://necrometrics.com/index.htm). Leading journals are *Holocaust and Genocide Studies* (since 1986) and the *Journal of Genocide Research* (since 1999).

Major Subjects of Genocide Research

Historical, sociological, and sociopsychological studies of genocide aim at the assessment of genocidal potential as well as the formulation of means to prevent the crime. Interventions against ongoing genocides are rather dealt within studies of warfare than in comparative genocide research. Eight predictive economic, demographic, ideological, ethnic, and ethical variables indicating genocidal potential have been identified: (1) a history of minorities outside the moral obligation of the majority (e.g., Jews, Armenians, Chinese); (2) a relevant percentage of young men with no hope for positions to satisfy their ambitions (youth bulge); (3) a preponderance of Marxist–Leninist, clericalist, nationalist/tribalist, racist, and/or other antihumanitarian ideologies; (4) an accepted political role for the military; (5) at least one totalitarian political party in power or well positioned to conquer it; (6) the totalitarian party has territorial claims against neighbors; (7) a civil war is waged against the internal resistance and/or a war against neighbors to realize these aims; (8) the legitimate secrecy in times of war is used as a cover for the killings with those minorities most vulnerable which have no retaliatory power of their own, no foreign allies or are hardly known to the rest of the world (for a pioneering work see Porter, 1982; cf also Stanton, 1998).

The prevention of these crimes requires an early warning system. Of the many failed attempts to establish 'Genocide Watch' (term created by this author) *The International Alliance to End Genocide* by Gregory Stanton has been the most enduring (http://www.genocidewatch.org/home.html). Israel Charny's *Genocide Prevention Now* (GPN; http://www.genocidepreventionnow.org) is online since 2010. On 23 April 2012, US President Obama declared, at the *United States Holocaust Memorial Museum*, that preventing mass atrocities was a 'core national security interest.' The declaration is an offshoot of the United Nations' RtoP initiative of 2005. That norm (not a law) focuses on preventing and halting four *Mass Atrocity Crimes* – genocide, war crimes, crimes against humanity, and ethnic cleansing (Evans, 2008).

Historically, only a minority of high-risk nations have transformed their perpetrator potential into actual genocide (the rate is higher for democide). Since a genocide needs preparation, all nations with perpetrator potential have to be scanned for red alert signals. At least six – difficult to conceal – indicators for the imminence of a genocide have been identified: (1) registration and/or marking of prospective victims; (2) staging a propaganda campaign which paints the prospective victims (most frequently the Jews of Israel) as a mortal danger to the prospective perpetrators; (3) ousting of police or military leaders who refuse to join in genocide operations; (4) recruiting and training of special killing units (Cete (Young Turks), Tsheka (USSR), SS (Schutzstaffel; Hitler Germany), Chetniks (Serbia), Interhamwe (Rwanda), etc.); (5) employing new euphemisms like 'ethnographic restoration' or 'final solution' (Hitler on Poles and Jews, respectively), 'ethnic cleansing' (Serbs on fellow Yugoslavians), 'civil war' (Hutus on Tutsis), etc.; (6) sudden appearance of – nonfamine or disaster-induced – refugees belonging to endangered minorities.

To predict genocidal potential within movements not yet capable of reaching national positions of power, a special grid of 14 or more designation points was developed to scan them (Littell, 1969: Chapters 2 and 3). A red alert pattern is reached when 8–10 actions are detected: (1) The cadre prints, distributes, and uses prejudicial material for attracting sympathizers and recruiting members. (2) It makes prejudicial appeals through the media or in mass meetings against any ethnic, religious, or cultural community. (3) Members cultivate the politics of verbal assault and physical violence-publishing slanderous charges, bombing meeting places and homes and media, beating and assassinating opponents. (4) The cadre pursues the politics of polarization, scorning the middle ground of compromise or consensus, rejecting the politics of moderation and orderly change. If it becomes numerous enough, instead of functioning as a parliamentary opposition it builds the structures of 'a state within a state.' (5) It uses the *Language of Assault* toward political opponents, rather than using the *Language of Dialogue* and participating in good faith in the political forum. (6) It deliberately drives a wedge between the generations, creating youth groups hostile to their parents' generation and to their heritage. (7) The cadre maintains camps for paramilitary training, including the use of antipersonnel weapons, outside the control of public officials (either police or

military). (8) It trains and maintains private armies, demonstrating in public in uniform, parading and marching to intimidate loyal citizens. (9) Leaders of the movement elaborate a quasi-religious structure of authority and sanctions, with political hymns, shrines, martyrs, and liturgies. (10) Archaic tribal, clannish, or religious symbols are worn by members as recognition signs, etc. (11) Induction and termination of membership are observed as quasi-religious rites. Straying members are treated as 'heretics.' (12) The movement's basic unit is the closed cell, with three to seven the standard number. This is the classic unit of a revolutionary party or intelligence operation, but it lies outside the style appropriate for loyal citizens to use in exercising influence upon a legitimate government. (13) The movement practices deception and confuses public opinion by launching one-issue 'fronts' – without clear identification of sponsorship, financing, and control. A great deal of money is raised this way, ostensibly for some good public purposes – but actually to serve the party's internal interests in the pursuit of power. These devices are known as 'the large net' within which 'innocents' are caught. (14) The cadre's studied tactics include infiltration and subversion of public institutions and voluntary associations, turning their direction from public service to bolstering the movement's drive for power.

Less developed concepts are scenarios for postgenocidal reconciliation. Even the systematization of Germany's pertinent efforts – so far second to none – is still in its infancy (Heinsohn, 1997). Low-key approaches like Truth Commissions are much more advanced. They were first tried, in 1974, in Uganda. By 2012, at least 23 nations had experience with such commissions (Hayner, 2001; Martin, 2009).

History of Genocide

Tribal (Primitive) Society

Genocide and acts of war were hardly distinguishable in tribal societies – covering the longest stretch of human history – because there was no separation of noncombatant civilians and warriors. Warfare was "'ecological' in motivation" and led to the redistribution of hunting and fishing grounds or arable land 'from the weak to the strong' (Keegan, 1993: p. 101). These wars were characterized by 'battles of annihilation' or, if space allowed, 'displacement of the weaker' (Keegan, 1993: pp. 29, 387). However, due to a lack of reliable data up to second millennium CE or later we simply cannot know to what degree tribal societies engaged in such atrocities. Much of what Europeans have reported as inhuman cruelty may just have been the desperate reaction against merciless invaders. Still, we know that genocidal tribal raids continued well into the second half of the twentieth century in territories of the Amazon, New Guinea, the Philippines, and elsewhere: "Typically the goal in such raids is to destroy an entire village or settlement, the common intention being to kill everyone, perhaps excepting a few of the younger women and children who are carried off for incorporation into the home group" (Glick, 1994: p. 45).

In resisting conquering European powers entire tribes – not only their adult males – went to war and perished together. A typical example is provided by the Hereros. By employing the most efficient technique of genocide – artificial famine – imperial German troops under General von Trotha, in 1904, drove them into the Omaheke desert (South West Africa), blocked the escape routes and let them die of thirst (Zimmerer et al., 2008). The annihilation, e.g., of the Tehuelche and Puelche by Argentina (1878–85; Hasbrouck, 1935; Maybury-Lewis, 2002: p. 45) or the Ndebele (Zimbabwe) by Great Britain in 1896/97 (Dodds, 1998) was executed in a similar manner.

Antiquity/Feudalism (Bronze Age)

The first stage of civilization (Early and Middle Bronze Age with priest-kingship feudalism) saw tribal genocidal practices on a larger scale. Tiglath-Pileser I of Assyria (conventionally dated from 1116 BC to 1077 BC) may exemplify this practice for Mesopotamia: "I burned their cities with fire, I devastated, I destroyed. / I captured, I killed multitudes of them. […] Their orchards I cut down" (Luckenbill, 1989: pp. 75/99). "I caught the survivors and impaled them on stakes in front of their towns" (Pritchard, 1969: p. 276). After unconditional surrender, pledges of loyalty and payments of tribute the victor may have granted mercy but there was no international law binding him to it as the same ruler made clear: "I destroyed them. The rest of their host embraced my feet, and I had mercy upon them. Tribute and tax I laid upon them, and counted them among the subjects of Assur" (Luckenbill, 1989: p. 80).

Further west, Egypt behaved in the same way: "I slew them without sparing them, they sprawled before my horses, and lay slain in heaps in their blood," Ramses II (conventionally dated from 1279 BC to 1212 BC) boasted after a campaign against the Hittites whose leader begged him for mercy: "Look, you spent yesterday killing a hundred thousand and today you came back and left no heirs. Be not hard in your dealings, victorious king" (Lichtheim, 1976: pp. 70f.).

In the West, the Greek expedition against Troy (conventionally dated to the twelfth-century BC) matched the campaigns of Asian and African rulers: "My good Menelaos' (king of Sparta), said he (Agamemnon, king of Mycene), 'this is no time for giving quarter. Has, then, your house fared so well at the hands of the Trojans? Let us not spare a single one of them – not even the child unborn in its mother's womb; let not a man of them be left alive, but let all in Ilius (Troy) perish, unheeded and forgotten'. Thus he did speak and his brother was persuaded by him, for his words were just" (Homer, 1952, *Iliad* VI: pp. 55–62).

The prototype of Western man, Ulysses, did not fail to live up to the same standard of justice: "When I had set sail thence the wind took me first to Ismarus [Thracia], which is the city of the Cicons. There I sacked the town and put the people to the sword. We took their wives and also much booty which we divided equitable amongst us so that none might have reason to complain" (Homer, 1952, *Odyssey* IX: pp. 39–42). Three millennia later, in Srebrenica – not that far from Ismarus – Bosnian Serbs dealt, on 11 July 1995, with Bosnian Muslims very much in Ulysses' manner. They separated 7000 males from their families and shot them. Before and after they raped young women left alive for that very purpose (Rohde, 1997; Nuhanovic, 2007).

The still pagan Early Israelites were hardly different from their neighbors: "Now go (Saul, 1st king of Israel; from 1022

BC to 1002 BC) and smite Amalek, and utterly destroy all that they have, and spare them not; but slay both man and woman, infant and suckling, ox and sheep, camel and ass" (*1 Samuel* 15: pp. 2–3). However, with monotheistic Judaism a set of moral rules was set down that has inspired antigenocidal legislation from its very beginning in the sixteenth century (see below).

Antiquity/City States (Iron Age)

The genocidal practice of time immemorial was cast into a principle by Athenians. When, in the Peloponnesian War (431–404 BC), Athens decided to wipe out Sparta's ally Melos, the admirals in charge tried to formulate an eternal law underlying their action: "It is a general and necessary law of nature to rule wherever one can. / We are merely acting in accordance with it, and we know that you or anybody else with the same power as ours would be acting in precisely the same way." After a few attempts at defending themselves "the Melians [in 415 BC] surrendered unconditionally to the Athenians, who put to death all the men of military age whom they took, and sold the women and children as slaves. Melos itself they took over for themselves, sending out later a colony of 500 men" (Thucydides, 1954, *The Peleponnesian War*, V: pp. 85ff.).

As a first step away from mutually slaughtering their males, the Greeks developed the practice of exchanging prisoners of war. Within the Roman Empire the practice of destroying enemies who had caused problems in the past was continued. The annihilation of Corinth (metropolis of mainland Greeks) and Carthage (metropolis of Phoenicians) in 146 BC, of Numantia (capital of Spanish Celtiberians) in 134 BC, or the elimination of the Etruscans (92 BC) and the Samnites (82 BC) as major opponents in Italy proper provide typical examples with 50 000–150 000 dead in each case. Of course, the opponents acted in the same manner as, e.g., in the slaughter of the inhabitants of the Greek cities Selinus and Himera (Sicily) in 409 BC by the Phoenicians of Carthage. However, within the Roman Empire a 'ius gentium' was developed for strangers who did not hold citizenship with – sometimes – more protection for these minorities than for full citizens.

The concept of 'politicide' – the elimination of local rivals for positions of power – was also already practiced in the Greek City States. Periander, despotic ruler of Corinth, had asked Thrasybulus, in the same position at Miletus, "about the safest political establishment for administering the city best. Thrasybulus led out Periander's messenger, outside the city, and with him entered a sown field […] And ever and again as he saw one of the ears of corn growing above the rest he would strike it down, and what he struck down he threw away, until by this means he had destroyed all the fairest and strongest of the corn. […] Periander understood the act of Thrasybulus and grasped in his mind that what he was telling him was that he should murder the most eminent of the citizens" (Herodotus, 1987, *The History*, V: 92).

The best known example of politicide in modern times was the annihilation, after eight inconclusive civil wars, of the Protestant leadership of France (*c.*100 000 victims), starting on Saint Bartholomew's Day (24 August 1572) when the Huguenots – easily recognizable by their black clothing – were guests at the royal marriage of Henri of Navarra and Marguerite of Valois (Garrisson, 2000). The politicide, in February 1570, against Novgorod, Russia's richest city, by Ivan IV (the Terrible) was peculiar insofar as the tsar had put together special killing units – the 'Oprichniki' – because the army was not trusted to act ruthlessly enough (Skrynnikov and Graham, 1981: pp. 213ff.). The suppression, on June 30 of 1934, of the so-called Roehm revolt in which Hitler's Gestapo assassinated more than 90 left wing Nazi leaders (Gritschneder, 1993). Above are well-researched politicides of the twentieth century.

Politicide does not necessarily include the killing of the families of the victims. However, in a so-called 'Vesper' – a politicide that is turned against a foreign elite – can easily grow into a full-blown genocide. It took its name from the Easter (=Vesper) festival in Palermo on 29 March 1282, when the French in control of the Kingdom of Sicily were killed with their families ('Sicilian Vespers'; Runciman, 1958). It had been preceded, in 1268, by the butchering of some 5000 members of the German Hohenstaufen elite of Sicily by the hands of the French conquerors. The earliest well recorded Vesper took place in 88 BC when all the Romans and Italians – including women and children – living in Greek Asia Minor were put to the sword by orders of Mithradates VI (Mayor, 2010). The Romans and Italians living in Britannia met a similar fate in 61 BC. In the 'Ulster Massacre' at Portadown (23 October 1641), the last Vesper of Western Europe, Irish rebels killed some 100 protestant British settlers and administrators (MacCuarta, 1993). The Creoles of Haiti delivered their French masters a Vesper in 1791/1805 (Dubois, 2005) as did, in 1857/58, albeit with no lasting success, the Sepoy to British masters of India (Anderson, 2007).

Parallel to genocidal practices of Greek City States, monotheistic Judaism – evolving after the Babylonian exile (conventionally ending in 539 BC) – began to formulate a code of ethics that – very slowly – came to influence international ethics. To overcome expectations of salvation tied to the ritual slaughter of humans and animals, the prophets found a new moral vision: "I desired mercy, not sacrifice; and the knowledge of God more than burnt offerings" (*Hosea* 6:6). The sanctity of life became the highest principle: "Thou shalt not kill" (*Exodus* 20:13; *Deuteronomy* 5:17) including – in its universal character – the strict outlawing of infanticide. The Torah emphasizes the sanctity of life as the core of the law and as a value identical with goodness ('the good law'):

> See, I have set before thee this day life and good, and death and evil. / Therefore choose life, that both thou and thy seed may live. / The stranger who dwelleth with you shall be unto you as one born among you, and thou shalt love him as thyself. / Keep thee far from a false matter, and the innocent and righteous slay thou not; for I will not justify the wicked. / If thou forbear to deliver them that are drawn unto death, and those that are ready to be slain. If thou sayest, "Behold, we knew it not" - doth not He that pondereth the heart consider it? And He that keepeth thy soul, doth He not know it?
>
> *Deuteronomy* 30: 15/19; / Leviticus 19: 34; / *Exodus* 23: 7; / *Proverbs* 24: 10–12.

Against monotheistic Judaism, the first recorded order (of Haman) for an ideological – though abortive – genocide (also called religiocide) was issued in the Ackhaemenid Empire of the fourth-century BC: "There is a certain people scattered abroad / and their laws are diverse of all people. […] And the

letters were sent by posts into all the king's provinces, to destroy, to kill, and to cause to perish all Jews, both young and old, little children and women, in 1 day" (*Esther* 3: 8/13).

Christians who had adopted the Jewish rejection of blood sacrifice to planetary deities actually suffered the first documented religiocide. The edict of Emperor Decius of CE 250 forced them to sacrifice to the pagan gods and eat sacrificial meat or suffer death (Bleckmann, 2006).

Middle Ages

The Middle Ages saw attempts at a 'Pax Romana' monitored by the Papal See. Its concept of a 'Pax Dei' (peace of God) – developed since CE 975 and extended over all Christian lands – outlawed war from Wednesday night to Monday morning as well as on Christian holidays. Excommunications and interdicts were the only means of enforcement. It was the beginning of international law based on the Judeo-Christian code of ethics. Yet, frequent transgressions were severe and – in modern terminology – genocidal.

The crusades – starting in CE 1096 – not only brought massacres of thousands of Jews in Germany and ten thousands of Jews and Muslims in Jerusalem (CE 1099), but also of fellow Christians. Against Pope Innocent III's interdict, Dalmatia's port Zadar – arch rival of Venice – was bathed in the blood of all its inhabitants in November 1202 during the 4th Crusade by French and Italian troops transported on Venetian ships. The same men – for a starter – butchered 2000 inhabitants of Greek Constantinople on 13 April 1205. Before the Latin army set mankind's finest city on fire it went on a three-day rampage of indiscriminate slaughter, not sparing women and children (Philipps, 2004).

Since 1167, the Cathars (from Greek katharoi = pure), called Albigensians after the French city of Albi, suffered a series of religiocides by Catholic forces because they rejected any spilling of blood and did not believe in the resurrection of Christ or the Holy Communion as the residue of blood sacrifice within Christianity (Pegg, 2008). By 1234 the Cathars were wiped out. In 1208, Innocent III who had tried to protect Zara and Constantinople, ordered the massacre of Béziers, a center of the Cathars, where most of the 15 000 inhabitants were slaughtered or burnt in their churches (Berlioz, 1996).

A few years later, in CE 1211, Gengis Khan's Mongols – with no authority to arouse their conscience by threats of excommunication or invoking the image of all men as protected children of the one God – began their terrifying campaigns from Japan to the Baltic Sea. To turn China's fertile areas into horse pastures the Mongols have, up to CE 1290, eliminated some 25 million Chinese. Another 5 million people perished in Persian, Arab, and Christian territories where the Steppe warriors revived the memory of Attila's fifth-century Huns. Behind their lines, the Mongols used to kill everyone perceived as a future threat, i.e., all males not suitable to join their ranks. Defeated armies were allowed a brief lease on life by serving as shields or battering rams for advancing Mongol troops. Tamerlane, a pious Muslim, let, in a single day of 1398, some 100 000 Hindus be strangled in sight of the walls of Delhi, which had rejected surrender. In 1402, he dealt a mortal blow to Arab civilization by killing 90 000 inhabitants of Baghdad (Morgan, 1986; May, 2007).

Early Modern Times

A sovereign's right to war ('ius ad bellum') dominated the period of sixteenth to nineteenth century in which Europe came to dominate the world. What happened within a war was more or less up to the sovereign. In Europe as well as overseas, the results were clearly genocidal. Tenochtitlan, the Aztec capital in the valley of Mexico with its 100 000 inhabitants, was annihilated by Cortes' Spaniards in 1521 (Sánchez, 2004). Around 20 000 inhabitants of German Magdeburg, the richest city of Protestantism, were slaughtered on 10 May 1631 by Catholic troops under General Tilly in the 30 Years' War (Lorenzen, 2006).

Yet, in response to the extermination of indigenous Americans at the hand of Spanish Europeans, scholars began to set down most of the principles that have guided international criminal law ever since. Thus, the Dominican friar of Jewish converso descent, Francisco de Vitoria (1483–1546), stated in *De Jure belli Hispanorum in barbaros* of 1532:

> Diversity of religion is not a cause of just war. Extension of an Empire is not a just cause of war. / Wrong done is the sole and only just cause for making war. // The deliberate slaughter of the innocent is never lawful in itself. This is proved, firstly, by Exodus, ch. 23: 'The innocent and righteous slay thou not.' / It is not lawful within a State to punish the innocent for the wrongdoing of the guilty. / Hence it follows that even in war with the Turks it is not allowable to kill children. / And the same holds with regard to the women of unbelievers. / On this principle it follows that it is not lawful to slay either foreigners or guests who are sojourning among the enemy, for they are presumed innocent. / The same principle applies to clerics and members of a religious order / unless / they engage in actual fighting. / [It is] the obligation to see that greater evils do not arise out of the war than the war would avert. / It would not be right, for the purpose of assailing a few guilty, to slay the many innocent by use of fire or engines of war.
>
> Vitoria, 1532: Part III, Summary 10–11/13; // Chapters 35–37.

Parallel to the upbringing of Vitoria, a special knowledge, the expertise of birth control in the hands of midwives, was wiped out in Europe making his principles inoperative for centuries to come. To repopulate the Old World that had fallen from some 80–50 million inhabitants after the population catastrophe of the Black Death (1348–52) some 100 000 persons, mostly women, were put to death in the great witch hunt between 1350 and 1700 (Heinsohn and Steiger, 1999). As a consequence, the *European Population Explosion*, four centuries of youth bulges, pushed this small continent from 12 or 13 to 27% of world population between 1485 and 1914. This not only led to world domination but also to an increase of Europe's own population from 60 to 500 million between 1500 and 1916. In 1914, out of 1000 young men worldwide aged 15–29, 350 were either born in Europe or European in origin. They had no one to fear but themselves until their total fertility (children in a woman's lifetime) had fallen from five to six in 1890 to 1.5 in 1990.

During the *European Population Explosion*, some 60 million young Europeans, with the superior military technology of their ownership-based economies forced to innovate to meet the rate of interest, but too few positions in an overcrowded

continent, conquered their 'Lebensaum' (settlement space) in the Americas, Australia, Africa, and Northern Asia. In the wake of Europe's 'emigration,' a population of 55–85 million native Americans (low estimate of 8.4 to high of 112.5 million) for 1492 (Spanish conquest) was reduced by 85–95% around 1650. Even a reduction of 100–1.8 million of the indigenous population of the Western Hemisphere between 1490 and 1890 is not only considered due to emigration (Stannard, 1992) but also seriously contested by identifying epidemic diseases as the main killer (Cook, 1998).

Between 250 000 and 500 000 native Australians estimated for 1788 (British conquest) were reduced to 60 000 by 1921. All means of killing were employed. Yet, there is a controversy (Dawson, 2012) between those regarding outright genocide as the major cause of deaths (e.g., Reynolds, 1999) and others that do not deny massacres but see infections as the main culprit (e.g., Windschuttle, 2002).

Not much is known on internal African genocides before the twentieth century. However, between 1500 and 1870, the continent lost up to 20 million inhabitants into American slavery with 2 million dying on transports. The slave trade within Africa may have cost, for the same period, the life of 4 million. On the slave routes to – mostly Islamic – Asia, another 11 million may have perished in these gigantic democides (Rummel, 1994: p. 48). The depopulation of the so-called Congo Free State, between 1885 and 1908, by ruthless war, starvation, and diseases under Belgium's King Leopold II (1835–1909) is considered the most atrocious example of European colonialism in Africa with a death toll of 5 million (Forbath, 1977) to 10 million (Hochschild, 1998).

Twentieth Century to the End of World War II

The entire century is on record with close to 180 million victims of democide according to Rummel's (1997) statistics.

The Hague Conventions of 1899 and 1907 with "The Regulations Respecting the Law and Customs of War on Land" prohibited, in articles 22–28, the murder, ill-treatment, or deportation of enemy civilians and prisoners of war. The use of poison and special ammunitions was banned. Yet, a nation's harm to its own civilians was not taken into consideration. This had to wait for the 'Istanbul Trials' (Dadrian and Akçam, 2011) installed in January 1919 to inflict punishment on those responsible for the Armenian massacres. On 10 April 1919, Mehmet Kemal Bey, procurator of the province of Bogazliyan, became the first person executed for genocide, then called 'crime against humanity.'

In the Nuremberg Trials of Hitler-Germany's leadership (1945/46; Weinke, 2006) as well as in the Tokyo Trials of Imperial Japan's leaders (1946–48; Totani, 2009), *International Military Tribunals* sharpened the legal instruments for punishing perpetrators of crimes against humanity. After these first steps, however, punishment of this crime had to wait 45 years after passage of the UN Genocide Convention in 1948 for ad hoc tribunals to prosecute the perpetrators of 'ethnic cleansing' in Yugoslavia (1993) and – a year later – in Rwanda (genocide of Tutsis in spring 1994). On 1 July 2002, the *International Criminal Court* came into being as a permanent tribunal located in Rome (for its legal basis see Schabas, 2000).

The extermination of the Ottoman Armenians (1894–96; 1909; 1915/16; 1919/23) combined strategic, racial, and ideological intentions (Dadrian, 1997). A shrinking empire was to be consolidated by a homogenous Pan-Turkic population within an undivided settlement space under Islam as the only religion. That is why not only more than 1 million Armenians suffered genocide but also other Christian minorities like Maronites (1860), Assyro-Chaldaeans (1915), and Greeks (1915–23) with a combined death toll of some 440 000.

Since 1917, the Marxist–Leninist Regimes have killed around 110 million people (Rummel, 1994; Courtois, 1997) (**Table 1**). "One-party communist states are 4.5 times more likely to have used genocide than are authoritarian states" (Fein, 1993: p. 79). The killings came as a combination of politicides (elimination of like minded rivals for power), genocides (elimination of minority nations, mostly in the Soviet Union and Communist China), and ideological genocides (foremost the elimination of proprietors or ownership-'infected' people). The latter category became the largest victim group in history with some 50 million dead (55% in China, 40% in the Soviet Union, 5% in the other Marxist–Leninist regimes). The Marxist ideology that ownership caused the fettering of productive forces, crises, and mass poverty guided these mega-killings. Since, however, earning the rate of interest, which is tied to the creditory encumbrance of property, is the real engine of accumulation and technological progress, the Marxist expropriations stalled economic development. Before this nexus was sensed, the economic failures were usually blamed on sabotage and/or party comrades ideologically tied to the past. This analysis led to massive party purges like the 'Great Terror' in the Soviet Union (1934/36–38) with more than 7 million (Conquest, 1990) or the 'Cultural Revolution' in China (1964–75) with at least 3 million dead (Clark, 2008) while, from 1949 to 1976, some 27 million perished in the Laogai forced labor camps (Chang and Halliday, 2005; they give a total of 70 million victims of Maoism).

Annihilation through forced labor in camps was initiated by Trotzki on 26 June 1918. By 1922, 23 Soviet camps were at work forming the nucleus of Stalin's Gulag emerging in 1928 and eventually running some 8000 camps. Working people to

Table 1 Rough estimates of numbers of victims by genocides, politicides, and ideological genocides of Marxist–Leninist regimes

Soviet Union, 1917–87 (Stalin alone 20 million)	30–40 000 000
Red China plus Maoists before 1949	40–70 000 000
Khmer Rouge in Cambodia, 1975–79	2 000 000
North Korea, 1945 onward	1 700 000
Yugoslavia of Tito, 1941–87	1 100 000
North-Vietnam, 1945–87	1 700 000
Poland (deportations of Germans), 1945ff.	1 400 000
Chekhovslovakia (deportations of Germans), 1945ff.	240 000
Ethiopia, 1974–91	4 000 000
Albania, 1944–90	100 000
Communist Germany, 1945–52	96 000
Yugoslavia–serbia, since 1990	150 000

Rummel, R.J., 1994. Death by Government. Transaction Publishers, New Brunswick, NJ; Courtois, S. (Ed.), 1997. Le Livre Noir du Communisme: Crimes, terreur, répression. Robert Laffont, Paris; Chang, J., Halliday, J., 2005. Mao: The Unknown Story. Anchor Books, New York.

death became, in the long run, the most devastating killing tool of communism. It allowed the elimination of opponents by simultaneously using them for the creation of big projects – like canals, railroads, subways, etc. – to prove by 'miracles' the promised productive superiority of communism that otherwise was wanting.

Communists of the Soviet Union and Ethiopia turned the ancient siege tool of artificial famines into the most efficient killing techniques used so far. To crush national ambitions of the Ukraine, e.g., a Soviet made famine killed at least 3 million in the single winter (4 months) of 1932/33 (Snyder, 2010). Ethiopian communists managed to kill between 1 and 2 million peasants between 1983 and 1985 by the same means (Kissi, 2006).

Of all twentieth-century authoritarian regimes, Hitler's Germany was the most genocidal. Only its Fascist partner Croatia – albeit on a much smaller scale – came close. Since 1 September 1939, deformed newborn and mentally handicapped Germans as well as German soldiers severely wounded in the military campaign against Poland were killed by injections or in gas chambers. Close to 130 000 eventually ended in this genocidal euthanasia operation (Benzenhöfer, 2010). Later exterminations struck so-called socially inferior Gypsies ('drop-outs') as well as homosexuals, etc. A bigger target, however (outlined in the 'Generalplan Ost' (Masterplan East)), was 100 million Slavs (Czechs, Poles, White-Russians, Ukrainians, and Russians) living between Germany's Eastern border and the Ural Mountains, a territory marked to become German 'Lebensraum.' Seventy five thousand members of the Polish elite – most of them holders of academic degrees – were killed right in autumn 1939. The second Eastern campaign, against the Soviet Union (22 June 1941), was aimed at the direct killing of 30 million Slavs. Another 30 million were destined to be worked to death to lay the infrastructure for German settlements. The remaining 40 million were to be driven into Siberia with a calculated death toll of another 10 million. With 13 million Slavic civilians and prisoners of war killed by 1945, Hitler-Germany had fallen short of its 70 million goal but still had committed the largest genuine genocide of the twentieth century. Hitler-Germany's Eastern campaigns, thus, were not common wars (Hillgruber, 1993) but militarily forced genocides.

Parallel with Hitler-Germany's genocidal wars, the destruction of European Jewry – beginning 1939 in Poland and in full force since 25 June 1941 – was taking the life of 5–6 million Jews up to May 1945 (best overview Longerich, 2010). After more than 50 different theories research on the Holocaust is tangled up in perplexity. Joachim Fest (1992), the most experienced of all Hitler researchers, summarized more than 40 years of work: "I do not understand it [the murder of the Jews], and nobody who has ever been dealing with it has even come close […] to a convincing interpretation" (Fest, 2004: p. 3). Ian Kershaw, the highly respected English Hitler expert (1998a, 2000) goes along with his German opponent: "Auschwitz comes to the limits of what can be explained: historians can describe how it happened, but why it happened is a completely different question. // [Hitler was] / obsessed with a / hardly explainable desire for destruction" (Kershaw, 1998b: pp. 4f. // 2005: p. 36).

A minority position put forward by this author (Heinsohn, 1995, 2000; adopted by Léon Poliakov, 1996; Jonathan Friedman, 2011: p. 509) claims that Hitler wanted to reintroduce the archaic rights to (1) infanticide – to strengthen Germany internally by killing handicapped including newborn – and to (2) genocide – to give Germany strategic superiority externally – by annihilating the monotheistic people of the 10 Commandments whom he regarded as the first abolishers of these archaic practices. To Hitler, thus, the sanctity of life was the ultimate Jewish *Weltanschauung* (ideology), which could be eliminated like any other ideology – e.g., the communism of Red Army commissars, etc. – by exterminating its 'carriers.' To turn the entire German military into a gigantic SS, to change every German male into a killer was no small task. This would not work if the soldiers were time and again exposed to the Jewish code of ethics with the sanctity of life at its core. In August 1930, Hitler had diagnosed the influence of this Jewish code: "In every human being the Jew destroys the natural instinct of self-preservation."

As Marxists had found out by historical research that property was nothing natural and, therefore, could be abolished, Hitler had found out that sanctifying life was nothing eternal but a human Jewish invention that could be removed from Germany's consciousness by exterminating its standard bearers.

The World since 1945

Whereas during the war some 900 000 Japanese and some 600 000 German civilian victims of allied carpet and/or nuclear bombing may be categorized as crimes of war or democide, genuine genocide with a death toll of 3.3 million accompanied the treatment of German prisoners of war as well as the expulsion of 16 million ethnic Germans from Russia (since 1944), Eastern and Southern Europe, and the territories Germany had to cede. In the postwar world only the genocidal crimes of Communist China surpassed the perpetrations of Germany's neighbors.

Worldwide (exempting the Soviet Union and Communist China) there were 68 conflicts with at least 10 000 casualties from 1950 to 2010 with a combined death toll of 36 million (Heinsohn, 2010). More than 100 crimes fulfilling the definition of the UN Genocide Convention have been committed since 1945 (Harff and Gurr, 1996). In the three decades from 1980 to 2010 alone, some 80 distinct ethnic and religious groups – mostly in Africa, Asia, and Latin America – have been victimized with at least 20 of them going through full blown genocide: Aceh and Timorese (Indonesia), Albanians (Serbian Kossovo), Bosnian Muslims, Cambodians, Isaaq (Somalia), Kurds (Iraq), Mayans (Guatemala), Tibetans, Tutsi (Rwanda) as well as 12 first nations in Brazil.

Many post-1945 conflicts in Afghanistan, Africa, Indonesia, Latin America, and Pakistan run on ethnic divisions and usually include acts of genocide when strife erupts. The cause for conflict, however, cannot be found in ethnicity as such because many regions were ethnically diverse before, during and after periods of killing. Therefore, another factor must be at work. Youth bulges – driving Europe's violence from 1500 to 1945 – again are

the main candidate with these very regions multiplying, between 1945 and 2010, from 450 million to nearly 3 000 000 000 inhabitants.

The Future

To evaluate future chances of mass killing, a more precise approach can be tried by computing what the author has called the 'fratricidal war index' (Heinsohn, 2011). It expresses the ratio between 15- and 19-year-old young men entering the strife of life and 55- to 59-year-old men approaching retirement. The range stretches from 0.7 (Japan, i.e., 10 retiring men are succeeded by only seven young men) to more than 6 (e.g., Afghanistan, Palestine, Uganda, Yemen), where 10 retirees are followed by 60 angry young men ready to embrace any justification – religious, racial, economical, etc. – for fighting their way up. An index of 3 (e.g., Egypt, Libya, Saudi Arabia) or higher points to violence with genocide and cross border wars the least but gang warfare, coups, and civil wars the most likely outcome. Sub-Sahara Africa with most nations indexed 5 or 6 in 2010 may still face decades of bloodshed. However, the index also proves helpful for forecasting which nations will not return to major killings because their index has already peaked and fallen back to 2 (e.g., Lebanon, Tunisia, Turkey).

Since most powers honoring human rights have indexes below 1 with America marking the maximum of 1.2, humanitarian intervention has the best prospects in nations indexed 2.5 or lower. After all, how many times can aging nations send a family's only son or even only child into mortal danger to hinder 10 or 20 superfluous young men in youth bulge nations from killing each other?

Genocide: Social and Economic Aspects

Ross Kleinstuber, University of Pittsburgh at Johnstown, Johnstown, PA, USA

Abstract

This article reviews some of the major recent theoretical developments in the criminological study of genocide, discusses the possibilities for interdisciplinary theory integration, and discusses themes common among existing theories. This article of the existing genocide literature suggests that genocide is likely when a dominant group perceives a vulnerable and dehumanized group as threatening its position of dominance and the leaders of the dominant group are able to direct such insecurities into targeted violence in the absence of social control mechanisms. The article concludes by calling for empirical tests of these theoretical claims.

Introduction

According to Goldhagen, "[T]he problem of genocidal killing is worse than war. Until now, the world's peoples and governments have done little to prevent or stop mass murdering. Today, the world is not markedly better prepared to end this greatest scourge of humanity" (2009: p. xi). In the twentieth century, genocide claimed four times more lives than war (Alvarez, 2001: p. 10); yet, Goldhagen's indictment could be directed easily against criminologists too. As recently as 2005, Hagan et al. called out the discipline for its "denial and neglect of these crimes" and argued that criminology is capable of explaining genocide and other international law violations; rather, its failure to do so "itself needs explanation" (2005: p. 556). Although other disciplines – most notably political science – have studied and theorized about genocide, the unique perspective of criminologists is essential for a complete understanding of genocidal violence.

Fortunately, recent years have seen an increase in criminological interest in the study of genocide, and numerous theories have been offered. Although these theories are in their infancy and still require further empirical testing, they point to some important social, economic, and political factors that are likely at work during genocidal incidents: most notably dehumanization, threat, a vulnerable target group, fanatical leadership, and absent control mechanisms. These theories also point to the importance of developing a multidisciplinary approach that can expand understandings of genocide and allow each discipline to learn from the insights and perspectives of others. As such, this article reviews some of the major recent theoretical developments in genocide studies and discusses some of the commonalities among the theories that seem like promising avenues for theoretical integration, empirical testing, and policy making.

Political Science Theories

The academic study of genocide is the most mature in the political science literature, where the act is viewed as a form of political (rather than criminal) violence. Contemporary political theories of genocide can be divided into two main paradigms: strategic theories that look at the importance of war and ideological ones that look at genocidal leaders' motives (Straus, 2012). Strategic theorists have shown that government mass killings are more likely to occur during civil wars or armed uprisings (Ulfelder and Valentino, 2008) and have suggested that the territorial loss that occurs during war creates insecurity and threat that drive genocide (Midlarsky, 2005). Straus (2006) has claimed that war legitimizes violence, increases feelings of insecurity, and empowers hardliners. The ideological paradigm focuses on the motives and goals of genocidal leaders. According to Straus, "The most consistent focus in the literature is on ideological visions of and for the state …" (2012: p. 548). For example, Weitz (2003) focused on genocidal leaders' visions of racial or national utopia, and Harff (2003) found that 'exclusionary ideologies' are central in the beliefs of genocidal leaders. Integrating these two paradigms suggests that war contributes to defining some groups as enemies (Semelin, 2007) and that when leaders with visions of ethnic, racial, or national purity feel their positions of power threatened, they are likely to resort to violence against a threatening subordinate group in an attempt to maintain their grip on power and to establish a more homogenous polity (Straus, 2012).

The macro-level, top-down approach of political theories fails to consider the actions of those who carry out the violence. It is one thing to understand why the political elites seek to maintain power or create an ethnically pure state; it is quite another to explain how they are able to get the masses to overcome their moral prohibitions and start killing their neighbors, friends, coworkers, and classmates. It also fails to consider how the target group is selected. Humans are simultaneously members of multiple different groups. How does one group affiliation take primacy and why? Although the political theories are good for understanding the politics of genocide and the motives of leaders, from a criminological perspective, they leave many unanswered questions as to what social forces are at work, why genocide is likely to and able to take place, and what the relationship between the political elites and the ordinary citizens is like. As will be shown, however, the two ideas of threat and ideology are important contributions that dovetail well with the emerging

criminological theories and provide an excellent nexus for cross-disciplinary theorizing and testing.

Early Criminological Theorizing: Out-Group Hatred

Browning (1992) and Goldhagen (1996) both challenged the idea popular in the social psychological literature that Nazi Germany was overtaken by psychopaths who used the power of obedience to authority to convince the populous to follow their command. They both pointed out the times when Germans refused to comply with commands and noted Germany's long history of anti-Semitism, which caused most Germans to view the Jews as subhuman before Hitler's ascendency. Drawing from these historical accounts, Brannigan (1998) offered a criminological theory of genocide that suggests that genocidal propaganda often serves the purpose of forging in-group solidarity, which eliminates the normal inhibitions against killing out-group strangers. Brannigan (1998), however, suggested that propaganda campaigns like the ones waged by the Nazis are not necessary for the creation of such hostilities toward out-group members. Brannigan (1998) contended that intergroup conflict and prejudice may be one of the by-products of cooperative human society. He argued, "The coalitionist or 'tribal' instinct is at the core of human nature. We cooperate to compete. But the dark side of this sociability is group prejudice and an intolerance of out-groups. In fact, the maintenance of group boundaries is premised on instinctual hatred of the Other" (Brannigan, 1998: p. 271, citations omitted). He even claimed that as societies become more cooperative, they also become more violent, confrontational, and xenophobic.

On the basis of his reading of the literature, Brannigan (1998) claimed that the root of genocidal behavior is xenophobic out-group hatred, but he also realized that this was not enough to explain genocide. After all, if out-group hatred is a universal part of the human condition, it becomes meaningless in attempting to explain or predict genocide since it does not vary. According to Brannigan, "Evolution may have created numerous appetites and instincts, but cultures are mechanisms for both switching them on and exciting other 'instincts' or mechanisms that can curb them or switch them off" (1998: p. 273). The question is, what are those other factors that trigger xenophobic instincts to annihilate the 'Other'? In other words, what factors must be present and interact with dehumanizing beliefs to trigger genocide, and which group affiliations will take precedence?

Techniques of Neutralization

Drawing from the insights of Milgram's (1963) obedience study and using a speech from Heinrich Himmler to support his proposition, Neubacher (2006) proposed a theory of genocide based on Sykes and Matza's (1957) techniques of neutralization. Neubacher (2006) argued that the Milgram study teaches us that when orders are given by someone with a strong position of authority, the actor is able to see him- or herself as a tool and therefore not responsible for his or her behavior. In addition, he relied on Kelman's (1973) expansion of Milgram's work, which suggested that the routinization of an act and the dehumanization of the victim makes it easier for perpetrators to engage in massacres. Neubacher (2006) connected these ideas to three techniques of neutralization: denial of responsibility, denial of victim, and appeal to higher loyalties.

The challenge, of course, is to apply this theory to mass violence perpetrated by the state. It would seem that the neutralization needed to engage in such atrocities is far greater than that needed for involvement in traditional acts of delinquency. Neubacher argued, "States violating human rights use the same neutralization techniques as individuals. State neutralization, however, is spread via the state's propaganda machine, thus having a far greater impact than individual neutralization" (2006: p. 795). He then analyzed a 1943 speech by Himmler and pointed out the neutralization techniques employed by the Schutzstaffel (SS) commander; Neubacher (2006) concluded that neutralization theory offers an explanation for both state involvement and why ordinary citizens are able to perpetrate the violence needed. Something seems to be missing, however. Sykes and Matza's (1957) original theory applied to juvenile delinquents and was an attempt to expand Sutherland's (1947) differential association theory by explaining what exactly juveniles learned from each other. Sykes and Matza (1957) believed that juveniles learn the techniques of neutralization through peer interaction and peer pressure. Although this may apply to the propaganda campaign waged by genocidal states on their own citizens, it fails to explain why the state itself desires the destruction of the targeted population and how they learned their neutralization techniques. Whereas street crime is a relatively constant phenomenon with a fairly obvious motive and a steady supply of peers from whom another juvenile can learn the techniques of neutralization, it is not clear from whom states and leaders learn these techniques or why they seek to destroy the victims. In other words, what causes the state-level motivation and neutralization that leads to the propaganda campaign and the eventual genocide, and how can this theory be used to predict or prevent genocide? For example, Goldhagen (1996) pointed out that Germans had a long history of anti-Semitism (i.e., denial of victim), and did not need to learn to neutralize anti-Semitic acts. So why did the Holocaust begin when it did? What other conditions caused the Germans to turn their hatred of the Jews into overt actions of annihilation?

Recent Criminological Approaches

Recently, criminologists have started to acknowledge that genocide involves complex processes that occur contemporaneously and at multiple levels of analysis. So although these earlier theories are lacking, their main points are useful starting places for building complex, multilevel models, and criminologists have started to propose such models. Four of these theories – Winton and Unlu's (2008) integration of violentization and circumplex theories, Hagan and Rymond-Richmond's (2009) collective action

theory, Maier-Katkin et al.'s (2009) theory of social conformity, and Rothe and Mullins' (2009) integrated theory of international criminal law violations – are described in the following sections.

Violentization and Circumplex Theory

In an attempt to bridge the micro- and macro-level interactions present in genocide, Winton and Unlu (2008) proposed integrating violentization theory from the homicide literature and the circumplex model from family therapy research. According to violentization theory, violent criminal behavior is the result of a microlevel process of development that occurs in four stages: brutalization, defiance, violent dominant engagements, and virulency (Athens, 2003). In the brutalization stage, one learns about violence through experience, demonstration, or witnessing violence. In the defiance stage, one learns a belief system that helps to legitimate and justify violence, such as needing to use violence as a means of stopping violence. In the third stage, violent perpetrators test out what they have learned in the first two stages by actively engaging in violence, and in the final stage, the perpetrator has come to identify him- or herself as violent (Athens, 2003). Winton and Unlu (2008) applied these ideas to genocide and suggested that those individuals who engage in genocidal violence are prepared to act violently toward each other through assaults, threats, observation, and coaching; are presented with a belief system and violent repetition that justifies violence; are encouraged to start engaging in violent acts of 'collective self-defense'; and eventually come to define themselves as violent. Winton and Unlu (2008) added a fifth stage to genocidal violentization – extreme virulency – to address the fact that genocidal violence often involves brutalization beyond simple killing. At the macro-level, Winton and Unlu (2008) drew from the circumplex model, which suggests that families are better when they are balanced in regards to cohesion and flexibility (Olson and DeFrain, 1997). In other words, families that are too enmeshed or too disengaged and families that are too flexible or too rigid are likely to experience dysfunctions (Olson and DeFrain, 1997). In their theory, Winton and Unlu (2008) applied these concepts to societies.

In a study of 13 genocides from the twentieth century, Winton (2005) concluded that genocidal societies are overly rigid and enmeshed, and in their examination of the Bosnian genocide, Winton and Unlu (2008) determined that when there is a crisis or conflict in a society that is becoming more rigid with increasing group cohesion, they are less able to cope with the crisis and are more likely to engage in the violentization process. Furthermore, in his examination of court documents from both the International Criminal Tribunal for the former Yugoslavia and International Criminal Tribunal for Rwanda, Winton (2011) demonstrated how both societies went through the violentization process (see **Figure 1**). This theory attempts to explain both the macro- and the micro-level factors involved in genocidal processes: the level of social cohesion and flexibility plus the microlevel process of violence escalation. It also jives well with political theories. As Straus explained, "Genocide is the product of a process or spiral of escalation in which alternative strategies of violence might have been previously tried or exercised" (2012: p. 554). Yet, this theory fails to explain why societies become less flexible or more enmeshed and why the violence becomes genocidal or is even directed toward the target group. Even Winton and Unlu (2008) admitted that their theory is not useful for predicting and preventing genocide – just explaining the process post hoc.

Macro–Micro–Macro Theory of Collective Action

Using data from the Darfur genocide collected by the US State Department's Atrocities Documentation Survey (ADS), Hagan and Rymond-Richmond (2009) created and tested a collective action theory of genocide that also drew upon differential association and collective efficacy theory in an attempt to link macro- to micro- and back to macro-level processes. Using ADS data, Hagan and Rymond-Richmond (2009) found that genocidal intent was expressed at both the individual and the collective levels, so they attempt to create a theoretical model that is able to account for this dynamic. The thrust of their

Figure 1 Winton and Unlu's (2008) violentization and circumplex model. Reprinted with permission from Elsevier.

argument is that at the macro level, there was increasing competition for land and resources between Arabs and Africans and a state-led ideology of Arab Muslim supremacy that constructed the two competing groups. At the individual level, members of the Arab group internalized the dehumanizing images and then engaged in violent actions. These individual acts of violence combined into collective action, causing macro-level violence.

As shown in **Figure 2**, Hagan and Rymond-Richmond (2009) have proposed that an Arab supremacist ideology in Darfur was used to justify an Arabization policy in the face of growing resource competition. Because of strained resources, genocide provided many Arabs with the opportunity to acquire goods and property from their black African neighbors. Hagan and Rymond-Richmond (2009) proposed that these macro-level features led to a socially constructed division between Arabs and Africans in Sudan. These socially constructed identities, in turn, incited the use of racial epithets by individuals, which helped to dehumanize the targeted group. When these individual expressions of racial hatred were concentrated within a geographic and social location, they became aggregated into collective racial intent. This collective intent, however, needed to be transformed into a violent fury that connected the racial intent to targeted violence. This is the final link in their model, in which a genocidal state directs the anger and hatred of a group into lethal destruction. Once the fury of one group has been unleashed onto another group, violence becomes genocidal. A key point for Hagan and Rymond-Richmond (2009) is that some kind of spark must ignite the angers and fears of the dominant group; they hypothesized that this spark is racial and collective. They suggested that their macro–micro–macro model explains both the state's involvement in genocide and "how and why ordinary people enlist in genocidal killing" (Hagan and Rymond-Richmond, 2009: p. 168). Hagan and Rymond-Richmond (2009) provided compelling evidence from the Darfur genocide to support their theory, including evidence that racial epithets were linked to increased severity of attacks, that the state was instrumental in leading the genocide and in identifying black Africans as the target, and that competition for resources and land intensified.

Theory of Conformity

Using the 1941 massacres of Jews in Jedwabne as a case study, Maier-Katkin et al. (2009) developed a theory of crimes against humanity (including, but not limited to, genocide) based on conformity. Drawing off of strain, social learning, and differential association theories, they presented a theory composed of six propositions: social strain and angry aggression, primary group affiliations, normal processes of socialization, group structure, ideology and self-interest, and displacement.

According to their first proposition, a necessary (but not sufficient) precondition to any crime against humanity is "intense and widely prevalent societal-level strain—caused by insecurity, danger, scarcity, deprivation, political and economic oppression, and/or military occupation," and that the more intense the strain is, the more likely a crime against humanity is (Maier-Katkin et al., 2009: p. 239). They argued in their second proposition that this "societal-level strain produces widespread individual-level fear, arousal and angry aggression" (Maier-Katkin et al., 2009: p. 241). This insecurity inhibits intergroup solidarity and drives people to seek safety in their most immediate primary groups. The third proposition is that once intergroup solidarity breaks down, primary group socialization takes on increased importance and can cause individuals to participate in horrific acts of violence. In other words, rather than being deviant, crimes against humanity are the result of conformity to social roles and expectations of the immediate social group (i.e., appeal to higher loyalties). Drawing off Milgram's obedience studies and Zimbardo's prison experiment, the fourth proposition is that during times of societal strain, individuals are more submissive and more accepting of social roles, thus giving socialization more influence. In this stage, leadership is crucial. If those in positions of influence happen to be

Figure 2 Hagan and Rymond-Richmond's (2009) macro–micro–macro transformation model of genocide. Reprinted with permission from Cambridge University Press.

reasonable or moderate, there is a strong likelihood of avoiding atrocities; if, however, radical elements that appeal to emotion take control, the stage is set for mass slaughter. Fifth, there also must be some ideology that motivates violence. It is not enough to have strain, fear, and intensified in-group solidarity. For crimes against humanity to occur, Maier-Katkin et al. stated there need to be "belief systems that dehumanize others, justify or recommend violence and associate 'higher' values with immediate self-interest" (2009: p. 246). Finally, when the first five propositions are present, for crimes against humanity to occur, the perpetrators need to have a nonthreatening scapegoat to target. If the aggression is directed at the actual source of strain, it represents self-defense or resistance rather than a crime; however, when the actual source is not vulnerable, the anger and aggression of the stressed group may be displaced onto a vulnerable group, if such a group exists. These six propositions provide a guide for understanding genocidal processes and also suggest that crimes against humanity cannot be studied as pathological or deviant. If we are to understand the actual criminal acts, we need to situate them within their context and understand that they are often a result of conformity to existing (but changing) social norms. Furthermore, numerous interacting factors are needed in sufficient quantity. None of the variables discussed by Maier-Katkin et al. (2009) are sufficient by themselves. They must coexist in just the right volatile mixture to produce crimes against humanity.

An Integrated Theory

Finally, Rothe and Mullins (2009) proposed an integrated theory of international criminal law violations. Like the other theories reviewed in this section, Rothe and Mullins (2009) believed that a single level of analysis is insufficient to explain such complex crimes. Drawing on theories of socialization, social learning, symbolic interaction, anomie, control, phenomenology, routine activities, and deterrence, Rothe and Mullins (2009) suggested that four forces operate at each the international, macro, meso, and micro levels of analysis: motivation, opportunity, constraints, and controls. Routine activities theory presumes motivation simply exists, but Rothe and Mullins (2009) believed that it is essential to explain motivation when trying to understand international crimes. In other words, some motivation is needed for the state, the organization, and the individual actors to engage in such crimes. These motivations may include political power, economic or resource gain, revenge, or some other variable. Beyond motivation, there must be an opportunity to commit a crime. Motivated offenders cannot commit a crime unless they encounter an opportunity to do so. For an act as complex as genocide or some other international crime to occur, however, the illegitimate opportunity must extend beyond the individual to other levels. This would include things like a vulnerable population, international relations, global economics, military supremacy, diffusion of responsibility, and propaganda. Rothe and Mullins (2009) then added a crucial concept that is not considered by other theorists: the role of social control forces (i.e., capable guardians). According to them, once a motivated offender is presented with an opportunity, an international crime becomes likely in the absence of constraints and controls. According to Rothe and Mullins (2009), a constraint is an informal inhibitor – something that makes a criminal act more difficult. A control, on the other hand, either completely prevents an act or ensures that the act will be punished formally. Because they presume that punishments are more likely to deter potential international law violators than street criminals, the threat of punishments should be effective at preventing such crimes.

As shown in **Figure 3**, Rothe and Mullins used their ideas to develop a causal model in which "a variety of independent factors [come] together to influence, as a combined force, the manifestation of" an international crime (2009: p. 110). According to their model, although motivational and opportunity forces exist at all four levels of analysis, they all function through motivations and opportunities they create within individuals. Therefore, they theorize that opportunity at the international, meso, and macro levels combine to create micro-level opportunity. This micro-level opportunity then directly can influence the decision to offend and can produce micro-level motivation. In addition to the influence of micro-level opportunity, micro-level motivation is influenced by motivation at the international, macro, and meso levels. As with opportunity, micro-level motivation directly influences the decision to offend but not the actual commission of the act. Constraints and controls, however, exist outside of individuals. Therefore, controls and constraints at all four levels of analysis combine to create a constraint node and a control node, each of which directly affects the decision to offend. The decision to offend, the constraint node, and the control node then directly affect the actual commission of the crime. This theory has the advantage of suggesting clear causal connections among the various variables in the model; however, Rothe and Mullins (2009) provided no data to support their theory.

Conclusion: Connecting the Dots

Although these theories each provide slightly different conceptions about what causes genocide, there is substantial overlap regarding dehumanization, threat, vulnerability, and leadership. The clearest parallel is the presence of a dehumanization campaign. As Chalk and Jonassohn observed, "We have no evidence that a genocide was ever performed on a group of equals. The victims must not only not be equals, but also clearly defined as something less than fully human" (1990, pp. 27–28). Several other scholars have pointed out this reality, and each of the theories reviewed here identifies something similar. Brannigan (1998) identified xenophobia, Neubacher (2006) focused on techniques of neutralization, Winton and Unlu (2008) discussed belief systems and enmeshed cohesion, Hagan and Rymond-Richmond (2009) described the importance of supremacist ideology and racial epithets, Maier-Katkin et al. (2009) detailed the process of primary group socialization and the role of ideology, and Rothe and Mullins (2009) explained the importance of absent internal constraints. Each one of these concepts describes the important role of belief systems that promote strong in-group identification and dehumanize other social groups. Even the political science literature suggests that exclusionary or supremacy ideologies are central to comprehending genocide (Straus, 2012).

Figure 3 Rothe and Mullins' (2009) causal model of genocide. Recreated by author. Used with permission from Taylor & Francis.

In addition to having a dehumanized victim group, there must be some motivational force. A common thread among each of these theories is the motivational power of perceived threats to a dominant group position. The political science literature discusses the importance of the threat and insecurity that occurs during war (Midlarsky, 2005; Straus, 2012). According to Winton and Unlu (2008), some crisis is needed to initiate the violentization process, and in the defiance stage, individual perpetrators learn that the victim group is threatening and that they must kill them or be killed themselves. Hagan and Rymond-Richmond (2009) described the importance of resource competition, and Maier-Katkin et al. (2009) mentioned that societal-level strain and insecurity are the precursors to crimes against humanity. Lastly, Rothe and Mullins (2009) suggested that, among other factors, genocidal motivation can include political, economic, and ideological goals; anomie; and rewards. Despite their differences, each of these theories is describing a perceived threat (economic, social, or political) to the dominant group's position or survival that can be perceived at several levels of analysis. At the state or macro levels, political scientists suggest that leaders are likely to target groups perceived as threatening if they hold ideological visions of racial purity. At the meso and micro levels, this same process also may be at play. At the group level, Blalock (1967) hypothesized that intergroup violence against a minority group is likely to increase when the dominant group experiences either a political or an economic threat, and at the individual level, Blumer (1958) suggested that racial prejudice emerges out of a sense of relative group position and is more likely to appear when members of the dominant group feel their position of superiority threatened by a subordinate group.

Furthermore, vulnerability and leadership are important ingredients. Opportunity is a key component to any crime, and if there is no vulnerable group against whom aggression can be directed or that can be effectively scapegoated, a crime against humanity cannot occur. Yet, because genocide is an extreme form of group-directed and group-perpetrated violence, leadership matters. As Hagan and Rymond-Richmond (2009) described, a genocidal state needs to focus and concentrate individual and collective racial intent into genocidal violence and usually is needed to propagate the dehumanizing or supremacist ideology. Similarly, Rothe and Mullins (2009) mentioned the importance of authoritarian pressures at the meso level and of propaganda and the structure of government at the macro level. The fourth proposition of Maier-Katkin et al.'s (2009) theory talks about authority figures being important for directing the activities of primary groups, and Winton and Unlu (2008) implied that someone needs to brutalize potential genocidal actors and teach them the supporting belief system. As such, when theorizing about genocide, in addition to considering the social and economic factors of a society, one needs to consider the relative power and vulnerability of different groups as well as the structure and motives of the authority figures within a society. This is

why an interdisciplinary approach that incorporates the theories of political science is important. Political scientists already have focused attention on the role of those in power; by adding the criminological focus on social and economic conditions, individual actors, and differences across different sociodemographic groups, a more complete understanding of genocide can be achieved.

One final point to consider is Rothe and Mullins' (2009) important insight about the role of constraints and controls, which have the capacity to prevent genocide even if all the other necessary forces are present. In other words, the existing literature suggests that when a dominant group perceives that a vulnerable and dehumanized group is threatening its position of dominance, it is likely to engage in genocidal violence when their insecurities can be concentrated and directed against the vulnerable group by those in power and when there is an absence of formal and informal control mechanisms. As promising as these theories appear to be for understanding genocide and its causes, they never have been fully tested. Therefore, it is imperative that the variables suggested in these theories – dehumanization, threat, vulnerability, leadership, constraints, and controls – be operationalized and subjected to empirical testing to determine which social and economic forces actually influence the genocidal process, what their relative influence is, and what factors can be addressed to prevent genocide.

Genographic Project

Theodore G Schurr, University of Pennsylvania, Philadelphia, PA, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

The Genographic Project is a major international effort to assemble genetic data from populations located around the world and use them to reconstruct the migratory history of our species. A consortium of scientists based at 10 regional centers worked with indigenous human populations from various parts of the world to investigate their genetic history, while members of the general public learned about their genetic ancestry through having their own DNAs analyzed for sequence variation. These studies have expanded our understanding of human migration patterns around the globe, the dynamics of human settlement through time, the influence of religion, culture, and language on population genetic diversity, and the evolution of human mitochondrial and Y-chromosome phylogenies. Counting both indigenous and public participants, some 675 000 people have participated in the project, making it the largest anthropological genetics study ever conducted. In addition, the Legacy Fund has supported numerous educational and linguistic initiatives of indigenous communities, thereby helping them sustain their cultural and linguistic heritage.

Inception of the Project

The Genographic Project was conceived as an initiative for addressing fundamental questions concerning our origin as a species and dispersal around the world. While certain aspects of human evolution and migration had been defined by the time that this project began, such as the fact that modern humans speciated in Africa (e.g., Cann et al., 1987; Quintana-Murci et al., 1999; Ingman et al., 2000), many other details about the migrations that led to the settlement of other continents of the world remained unclear (e.g., Forster, 2004; Metspalu et al., 2004; Schurr, 2004). For anatomically modern humans, the major dispersals across the globe took place in the latter stages of the Paleolithic period, between 75 000–15 000 years ago.) In addition, relatively little was known from a genetic perspective about more recent events in human evolutionary history, such as those occurring over the past 10 000 years (e.g., Wells et al., 2001; Salas et al., 2002; Richards, 2003) or even more recently (within the last 1000 years) (Gresham et al., 2001; Zerjal et al., 2003; Yao et al., 2004). Thus, while anthropological research (linguistic, archeological, ethnographic, biogenetic) had helped to clarify some aspects of these questions (e.g., Polynesia: Bellwood, 1996; Oppenheimer and Richards, 2001), in other respects, geneticists had really only just begun to elucidate them.

The Genographic Project was officially launched in April 2005 at the National Geographic Society headquarters in Washington, D.C. Conceived and led by Dr. Spencer Wells, an Explorer-in-Residence at the National Geographic Society, the project was designed to substantially expand our knowledge of human ancestry, migration, and history and expected to run over the course of 5 years. To achieve this goal, a set of anthropological and human geneticists was assembled and tasked with undertaking project-related research in different areas of the world. These researchers were to conduct field research and collect DNA samples for genetic analysis that would allow them to address outstanding questions important to the regions in which they were working. By employing state-of-the-art technology for genetic analyses, project researchers would also increase the resolution of the genetic data being used to explore human migratory history. Moreover, by generating a large data set based on genetic markers analyzed in tens of thousands of individuals representing global population diversity, these data could be used to delineate large scale as well as more localized patterns of genetic diversity in different regions of the world.

Once the project was initiated, Genographic researchers began working with numerous indigenous populations living in traditional contexts to explore their genetic histories. Here, the term 'indigenous populations' refers to groups living in their natal territories or homelands and following traditional cultural practices, as described above. Hence, indigenous populations can be found in the Americas (Native Americans) and Australia (Aboriginal Australians), as well as Sardinia, Laos, Lebanon, and South Africa, among other places. These populations were targeted because they represented communities that have lived in their respective locations or territories for many generations, preserved many aspects of their traditional life ways and cultures, and remained relatively unadmixed with populations from other regions of the world. Due to increasing globalization and contact between peoples of different backgrounds, many indigenous communities are undergoing significant changes, with some of their members moving to urban areas and becoming integrated into the broader nonindigenous cultures. Because of these rapid cultural and demographic processes, the geographic and cultural context for the genetic diversity that these individuals bear could potentially be lost or obscured. Thus, the project was attempting to capture a genetic 'snapshot' of the history of our species before processes of modernization erased or blurred some of the patterns of genetic variation that reflected the ancient migratory history of our species.

At the end of the 5-year period, the Genographic Project planned to have created a public-domain anthropological genetic database that could be used by other scientists and the participants in the study to learn more about human genetic diversity. This database would also serve as a resource for educating the general public about the history of our species. An explicit goal of the project was sharing the benefit of

knowledge acquired during the course of the research efforts with participating indigenous groups and individuals.

While ambitious in its scope, the Genographic Project wanted to avoid some of the pitfalls of the Human Genome Diversity Project (HGDP) (NRC, 1997), an earlier attempt to survey global human genetic diversity (Weiss et al., 2002). Accordingly, the Genographic Project created a research framework that was informed by concerns raised over the HGDP. These included putting measures in place to protect the privacy of participants and maintain the anonymity of samples obtained for genetic analysis. Participants were informed that they owned their DNA samples, had full control over the use of them for this research project, and could withdraw from the project at any time during their involvement in it. The project also recognized that informed consent could involve both communal and/or individual consent, depending on the populations being consulted. To obviate concerns about biopiracy and exploitation of biological specimens, the project also explicitly stated that its researchers would not use DNA samples for medical testing or to generate cell lines for use in future human genetic studies. All DNA samples would only be used for the scientific objectives of the project, which were to map the migratory history of humankind over the past 200 000 years.

Due to the complexities of undertaking a global research study, the first phase of the Genographic Project went beyond the originally projected 5 years and continued through 2012. In the second phase of the project (Geno 2.0), which began in that year, researchers began analyzing additional DNA markers to gain a broader view of genetic variation in different human populations. This effort was stimulated by the creation of the GenoChip, an Illumina microarray designed to interrogate human genomes for autosomal, mitochondrial, and Y-chromosome variation (see below). The mitochondrial DNA (mtDNA) is passed down each generation from mothers to daughters, hence, represents maternal lineages in human populations. Similarly, the Y-chromosome is passed down each generation from fathers to sons, hence, represents paternal lineages in human groups. By contrast, autosomal DNA is passed down to children equally from each parent, hence, the markers or genes in the autosomes (chromosomes) are biparental in their inheritance. They reflect the contributions of numerous ancestors from both the mother and father's sides of the family. An expanded analysis of autosomal variation in Genographic populations is now in progress.

Overview of Project Objectives and Components

Objectives

The primary objective of the Genographic Project is to generate a global perspective on human genetic history by establishing and analyzing the world's potentially largest public database of genetic markers devoted to the study of human origins and migration. In collaboration with indigenous communities, the project intends to raise awareness in the global community about the threat to indigenous cultures and populations through the dissemination of unique narratives describing their histories. These efforts have also helped to build scientific capacity in developing countries through collaborations with local laboratories, scientific organizations, and researchers. Furthermore, the project has functioned as a unique educational platform that has enlarged public knowledge about genetics and human history, and also showed individuals in the global community how they are related to other people from around the world through their participation in the project.

Project Components

To achieve these goals, the Genographic Project initiated three interrelated components of the project, namely, Research, Education (Public Participation), and the Legacy Fund. These components are described in some detail below. Because the Genographic Project has been conducted in two phases, these components have been pursued to somewhat different extents over the 9 years that the project has been underway. For example, in Phase I, Genographic researchers collected the bulk of the DNA samples to be used for genetic analysis through field expeditions in various parts of the world. In Phase II, more limited fieldwork and sample collection has taken place, with most project work being focused on publishing research findings generated from and analyzing autosomal variation in DNA samples collected during Phase I. Each regional center initiated its part of Genographic Project research based on the dates at which its Principal Investigators (PIs) completed financial contractual negotiations with National Geographic Society, obtained research permissions in the countries in which the regional team wanted to work, and assembled the research team needed to undertake project research. Thus, where appropriate, further distinctions in the timing of work on different project components will be made in the text.

Research

The Research Component has been the primary focus of this project. Its main objective was to collect oral and family history data together with biological samples from people from different geographical regions of the world to help reconstruct the history of human migrations and interactions over the past 200 000 years. During Phase I, laboratory analysis was directed toward analyzing genetic markers in the mtDNA and Y-chromosome (NRY) that are useful for inferring genealogical relationships and discerning these historical migration patterns. Here, 'NRY' means the 'nonrecombining portion of the Y-chromosome,' the region in which most of the anthropologically informative genetic markers are found. No markers of known medical relevance were investigated.

A total of 10 research centers were established to conduct this research, each with its own PIs to direct this research. They included centers in North America (Theodore Schurr), South America (Fabricio Santos), West/Central Europe (Lluis Quintana-Murci, David Comas, Jaume Bertranpetit), Middle East/North Africa (Pierre Zalloua), Sub-Saharan Africa (Himla Soodyall), North Eurasia (Oleg Balanovsky, Elena Balanovskaya), Australasia/Pacific (John Mitchell, Elizabeth Matisoo-Smith), East/Southeast Asia (Li Jin), South Asia (Ramasamy Pitchappan), and Ancient DNA (Alan Cooper). The PIs assembled research teams of technicians, postdoctoral researchers, graduate students, and undergraduate students to conduct field and laboratory research in these regions. The

project also involved two Associate Researchers who served as technical and research advisors, these being Chris Tyler-Smith (The Wellcome Trust Sanger Institute) and Doron Behar (Family Tree DNA). Each of the 10 regional centers followed its own localized sampling and research agenda, with the overarching goal of working with as wide a range of populations as possible. During the course of Phase I, each center endeavored to enroll approximately 10 000 individuals in the project, for a total of 100 000 participants.

Education (Public Participation)

The Education, or Public Participation, component of the project invited individuals from around the world to participate in the real-time anthropological study that is, the Genographic Project. Public Participation kits were sold through the Genographic Project Web site. Participants used the buccal (cheek) swabs in the kits to obtain DNA samples for genetic analysis, and then sent the swabs to Family Tree DNA, which, in collaboration with the Arizona Research Labs at the University of Arizona, extracted and analyzed the DNA samples. All samples were analyzed for the basic set of genetic markers used for the Research Component of the project. Based on the resulting data, members of the general public were able to trace their own genetic ancestry and also donate their DNA test results to the project database for use in research studies.

Another important part of this component was the interactive Web site for mapping and presenting the results of Genographic Project research to the general public (https://genographic.nationalgeographic.com/). On the Web site, viewers could find details about the project, such as maps tracing human migration routes, descriptions of the genetic methods used in the project, updates on project related studies, and profiles of project researchers. Through this Web site, public participants could also access their own DNA test results, which include both their basic genetic data and a corresponding description of their ancestors' migratory and cultural journeys as inferred from these results, thereby promoting their understanding of the objectives and results of Genographic Project research.

The Legacy Fund

The Genographic Legacy Fund (GLF), funded by a portion of the net proceeds from the sales of the Genographic Public Participation kits, links the scientific side of the project and public participants to the indigenous communities. The GLF was also intended to reflect the values and missions of the Genographic Project funding partners, as well as raise awareness of the challenges facing indigenous groups while building community capacity. National Geographic Society's mission is to increase and diffuse geographic knowledge while promoting conservation of the world's cultural and natural resources. IBM is committed to providing diverse and sustained programs that support education, workforce development, arts, and culture, and communities in need on a global basis. The Waitt Family Foundation is dedicated to supporting projects that seek a deeper understanding of human history, expand the potential of the human mind and improve humankind's knowledge through historical and scientific exploration. The Genographic Project's Advisory Board, comprised of leaders from various scientific and other fields – including indigenous advocacy – provided oversight and guidance to foster meaningful community involvement and representation in the decision-making process surrounding the operation of the GLF. Overall, the GLF was designed to support indigenous communities and build capacity by funding relevant programs and projects initiated by these groups that would be sustainable beyond the established time frame of the Genographic Project.

Phase I

Research Component

Community Outreach and Engagement

To undertake this research, Regional Center PIs established relationships with individuals of a given community (e.g., tribal elders, village council members, members of a particular indigenous group, elected leaders, etc.). These relationships were developed through several means, including trips to the communities by project members to discuss the details of the project with them, and contacting anthropologists, archaeologists, and colleagues from medical fields who had previously worked, or are currently working, with these communities to initiate a dialogue with their leaders about the group's possible involvement in the project. Each center also developed collaborations with scholars working in different countries within the region for which the PI was responsible for working, with these individuals participating in sample collection and analysis.

Sample and Data Collection

Members of the Genographic scientific team chose populations to approach for participation in the project on the basis of different scientific or historical criteria, i.e., because their inclusion would help to answer specific questions about human migration history that were relevant to specific regions of the world. To work with indigenous populations, the PIs and their team, along with collaborators, traveled to the locations where these communities reside. As noted above, individuals from indigenous groups were chosen because they were more likely to have not experienced extensive recent admixture with other population groups, hence, to preserve a crucial record of their own and their communities' biological history and genetic ancestry.

Whenever possible, unrelated adult men and women were enrolled in the study. Researchers confirmed that individuals were genetically unrelated to each other through at least two generations through interviews, family history information, written genealogies, tribal and village information, and written documents in local and archival records. Such data were also invaluable for interpreting patterns of genetic variation within a population, as they provided insights into marriage patterns, places of residence, and family relocations.

Biological samples used for genetic analysis included buccal swabs, mouthwash, and blood samples, depending on the community involved in the research. The collection method was agreed with the participating indigenous groups and individuals during the consultation process. Upon their arrival at the regional center laboratory, researchers extracted DNA from the samples for genetic analysis. For ethical reasons, no transformed cell lines were established from any of the blood

samples collected in the course of the Genographic Project. In addition, no medically relevant information was collected from either the DNA samples or the participants themselves during interviews.

Human Subjects

The research teams followed local laws concerning genetic sampling and anthropological fieldwork, and obtained the requisite research permissions to work in each location. Project researchers obtained written or oral informed consent from participants, as specified in the permission requirements for each region, and asked them questions about their ancestry and duration of residence in the region. These included details about their family histories and genealogies, the language(s) that they spoke, and the oral histories of their communities. Following the interview, researchers then collected biological samples for DNA analysis.

Genographic Project IDs

All persons who provided samples were assigned a randomly generated alphanumeric code called a Genographic Project ID (GPID). Participants were able to use their GPIDs to retrieve their DNA test results and accompanying explanations from the secure public Genographic Web site. If individuals did not have access to the Internet and requested information about their results, researchers mailed the DNA test results to them or otherwise communicated these findings to the participants through an appropriate means.

Project Database

Raw genetic data were interpreted at the regional centers and prepared for database submission. The interpreted data were submitted to the central Genographic Database and Repository (DAR), which is being hosted at National Geographic Society headquarters in Washington, D.C. No identifying information obtained during the sample collection process was entered into the DAR. No one outside of the individual regional centers had access to the GPIDs such that the names and genotype data from participants could be connected. In addition, all family history information was securely maintained by the regional PIs and their team, and used primarily to interpret the genetic data. Such information was also very helpful in reporting the results of the genetic analyses to participants in the project, which, in turn, facilitated dialogue between the participants and the PIs about the nature and interpretation of their DNA data.

Genetic Data Reports for Participants

In addition to providing GPIDs to participants for accessing their DNA test results online, some regional centers produced a set of explanatory documents to send to all of their participants. These documents provided additional details to help participants understand the DNA test results. As such, they served as tools for educating participants about genetics and helping them to better understand aspects of their biological ancestry, complementing information accessible through the Genographic Web site. Genographic researchers also communicated project results to indigenous participants through return visits to their communities to present the genetic findings, preparing summary documents for tribal authorities, and having conversations with them via telephone and e-mail.

Laboratory Analyses

As noted above, laboratory analysis of the samples focused on analyzing genetic markers useful for inferring genealogical relationships, namely those found on the paternally inherited Y-chromosome and maternally inherited mtDNA. For the Y-chromosome, the markers included an array of short tandem repeats (STR) and single nucleotide polymorphism (SNPs) drawn from a more extensive list of Y-chromosome STR and SNP markers described in the literature (e.g., Kayser et al., 2001; Underhill et al., 2001; Butler et al., 2002; Jobling and Tyler-Smith, 2003; Y-Chromosome Consortium, 2002; Karafet et al., 2008). In addition, mtDNA sequences from the non-coding hypervariable segments I and II and lineage-defining SNPs located in the coding regions of the mitochondrial genome were analyzed (Torroni et al., 2006). In some cases, researchers sequenced whole mitochondrial genomes to obtain the highest resolution maternal haplotypes possible (e.g., Kong et al., 2003; Palanichamy et al., 2004; van Oven and Kayser, 2009). Standardized laboratory protocols for analyzing Y-chromosomal and mtDNA were used with ABI 3130XL Gene Analyzers and ABI 7900HT Real-Time PCR Machines based in regional center labs to characterize indigenous participant DNA.

Public Participation

For the Public Participation component of the project, subject recruitment occurred through information presented on the Internet, radio, television, and print media outlets. All members of the public were encouraged to participate, and the purchase of the kits was made through the project Web site, as explained above. Participants purchased swab kits and had their DNA samples analyzed, with the resulting data being sent from Family Tree DNA/Arizona Research Labs to the DAR. The data residing in this repository were accessible to participants at the project Web site through the use of their unique GPID identifiers. Upon viewing their DNA test results, public participants were asked if they wanted to include their data in the Genographic database. Those who decided to include their data in the DAR were also asked to complete a questionnaire about their family history, one very similar to that used with indigenous participants to assure the equivalency of demographic data collected from all participants in the project.

Research Support

The Genographic Project was financially supported by several partnering organizations, including the National Geographic Society, IBM, and the Waitt Family Foundation. During Phase I, the National Geographic Society provided support for laboratory analysis in the regional centers, IBM provided computational and software support, and the Waitt Family Foundation provided funds for field research in various parts of the world. Each PI also obtained additional funding through intramural and extramural sources to help carry out various aspects of project-related research.

Genographic Project Results: Phase I

Research Component

After 7 years of focused research, Genographic Project scientists have made a number of important contributions to our understanding of human migratory history and population dynamics. To attain these achievements, they worked with hundreds of indigenous communities and nearly 75 000 participants from around the world. Because many of these populations were not represented in existing sample panels (e.g., Altshuler et al., 2010; Durban et al., 2010; 1000 Genomes Project Consortium, 2010), the data obtained from their DNAs were novel and highly informative about the demographic and migratory history of the regions of the world in which they lived, as well as the specific histories of the participating communities themselves. Although page limits place constraints on a full description of the results of Genographic Project research to date, the following discussion summarizes many of the highlights of this work.

To begin with, Genographic research has elucidated the deeper branches of the human mtDNA phylogeny in Africa, particularly those found largely in contemporary Khoisan-speaking populations (Behar et al., 2008b). This study also suggested that the early settlement of humans in Africa was matrilineally structured and involved small, separately evolving isolated populations (Behar et al., 2008b). More recent work has revealed differentiation in the genetic affinities of Middle Eastern populations with African and European populations, with Y-chromosome data suggesting greater affinities with Africa and mtDNA data indicating stronger genetic affinities with Europe (Badro et al., 2013).

Related research with populations from the Near East has further defined the influences of history, geography, and religion on population genetic structure in Lebanon. Y-chromosome analysis indicated that Islamic expansion from the Arabian Peninsula in the CE seventh century introduced lineages typical of this area into populations that subsequently became Lebanese Muslims, whereas Crusader activity in the eleventh–thirteenth centuries CE introduced Western European lineages into Lebanese Christians (Zalloua et al., 2008a). Similar work also defined the genetic influences of Phoenicians around the circum-Mediterranean region during the flourishing of their trade empire (Zalloua et al., 2008b).

Y-chromosome studies have also illuminated the history of populations from other regions of the world. For example, in Afghanistan, an analysis of paternal lineages suggested that interpopulational differences emerged during the Bronze Age after the formation of the first civilizations in the region, with later migrations and invasion reshaping them, giving Afghans a unique pattern of genetic diversity in Central Asia (Haber et al., 2012). Related work showed the parallel evolution of genes and languages in the North Caucasus resulting from high levels of isolation, differentiation, and genetic drift *in situ*, due in part to the mountainous terrain of the region (Balanovsky et al., 2011). Likewise, Y-chromosome analysis demonstrated that population differentiation of male lineages in Southern India (Tamil Nadu) correlated with agricultural expansions that predated the formation of the caste system (Arunkumar et al., 2012).

Genographic research has provided fine-grained details about the population history of specific regions of the world. In Europe, ancient DNA (aDNA) analyses confirmed prehistoric gene flow from Siberia as part of the complex human population history of Northeast Europe (Der Sarkassian et al., 2013, 2014), and revealed that the formation of Central European mtDNA diversity occurred in several different stages (Brandt et al., 2013). A related aDNA study of the Linear Pottery Culture in Germany further demonstrated that this archeological population had affinities with groups from modern-day Near East and Anatolia, supporting a major genetic input from this area during the advent of farming in Europe (Haak et al., 2010). From a modern DNA perspective, the analysis of uniparental genomes revealed evidence of pre-Roman tribal genetic structure in Basques, who are otherwise linguistically distinct from their Indo-European speaking neighbors (Spanish and French) (Martínez-Cruz et al., 2012a), as well as evidence for partial genetic continuity of contemporary Basques with preceding Paleolithic/Mesolithic settlers of their homeland (Behar et al., 2012). In addition, Y-chromosome analysis of individuals bearing the Basarab name was used to examine the genealogy of the first dynasty of Wallachian kings in Romania, which included Vlad III the Impaler, also known as Dracula (Martínez-Cruz et al., 2012b).

Genetic data from Genographic studies have also contributed to our understanding of East Asian prehistory. The analysis of Y-chromosome lineage O3 diversity in Sino-Tibetan populations revealed that human groups entered the eastern Himalayas through two different routes (Kang et al., 2012). An analysis of mtDNA variation in Tibetans also indicated both pre-last glacial maximum (LGM) and post-LGM expansions into the region, with greater diversity in the southern part of the Tibetan Plateau suggested that it was a population refugium during the LGM (Qin et al., 2010). A Y-chromosome analysis of Mon-Khmer and Hmong-Mien-speaking populations also showed that human groups expanded from Southeast Asia into East Asia through a series of bottlenecks during the LGM, based on the distributions of lineages O3a3b-M7 and O3a3c1-M117 in the region (Cai et al., 2011).

Genographic research has made important advances in our understanding of the people of the Americas. A recent Y-chromosome analysis revealed genetic divergence and new founding native lineages in Athapaskan and Eskimoan-speaking populations of northern North America, with these data providing new insights into the human settlement of the Arctic (Dulik et al., 2012). Similarly, an analysis of mtDNA variation showed that clan, language, and migration history have shaped genetic diversity in Haida and Tlingit populations from Southeast Alaska (Schurr et al., 2012). In South America, researchers explored the genetic history of Uros populations of the Peruvian and Bolivian Altiplano, and found that they likely derived from ancient Andean lineages that were partially replaced during more recent farming expansion events and the establishment of complex civilizations in the Andes (Sandoval et al., 2013).

From a methodological standpoint, Genographic research has produced a number of new approaches for analyzing

genetic data. These included tracing patterns of chromosomal recombination to estimate the effective population size and the history of Old World human populations (Melé et al., 2012), using these same recombinational events to refine methods of producing gene trees (Parida et al., 2008, 2009), and taking knowledge about rates of mutation in DNA sequences to better identify the lineages to which they belong (Rosset et al., 2008). The effective population size (N_e) of a human group is the number of reproductively active individuals in it. Although N_e can be influenced by genetic drift and endogamy, it is usually less than the census size of the group. Project researchers have also created a new multiplex TaqMan genotyping assay for distinguishing most Y-chromosome lineages and sublineages in Europe (Martínez-Cruz et al., 2011), found new Y-chromosome SNPs in lineage Q through resequencing work (Jota et al., 2011), and developed an 'A to Z' protocol for obtaining complete human mitochondrial (mtDNA) genomes (Clarke et al., 2014).

An extended list of Genographic Project publications is provided in the Literature Cited, with a number of other manuscripts currently being in preparation or under evaluation at peer-reviewed journals. Collectively, they represent the enduring scientific legacy of this project.

Public Participation

Based on the enthusiastic response to this initiative, nearly 600 000 individuals from around the world have become involved in the Public Participation component of the Genographic Project. Their contributions to the DAR represent the largest database ever assembled for anthropological genetics research. In fact, an analysis of mtDNAs from approximately 80 000 individuals enrolled in the first 18 months of the study produced the largest standardized human mtDNA database ever collected at that time (Behar et al., 2007). This database was quite informative with respect to providing new details about mtDNA phylogeny and mutational dynamics, and also facilitated the development of a new nearest neighbor lineage prediction tool. Future work will utilize the abundance of mtDNA and Y-chromosome data obtained from public participants in similar fashion.

Legacy Fund

To date, the GLF has supported a number of initiatives by indigenous communities from around the world. These include the documentation of traditional Otomí stories in the Sierra of Xichú, a community located in Guanajuato State, Mexico; the recording of oral literature in Dangaura Tharu (an Indo-Aryan language) and in Limbu (a Tibeto-Burman language) in Nepal; the creation of a digital archive of the photographs, stories, and historical documents of the Cherbourg-Aboriginal settlement of Southeastern Queensland, Australia; and the revitalization of indigenous language and ecological knowledge on the Marquesas Islands in French Polynesia, among others. Additional details about the GLF can be found at the Genographic Project Web site: https://genographic.nationalgeographic.com/legacy-fund/.

Phase II: Geno 2.0

The second phase of the project, called Geno 2.0, began in late 2012. Its focus is the characterization of autosomal SNP variation in different human populations, as these data provide a more complete genetic history for individuals in encompassing contributions from many different ancestors. Based on recent studies, it is clear that genome-wide methods are becoming a crucial component of anthropological genetic studies (e.g., Li et al., 2008). This work is being partially supported by National Geographic through research grants awarded to Genographic Project researchers and other scientists interested in using the new GenoChip to conduct anthropological genetics studies, and supplemented by funds from other public and private organizations obtained by PIs from different regional centers.

More specifically, Genographic scientists and other investigators are analyzing autosomal SNP variation in human DNA samples (many collected during Phase I, some previously obtained in unrelated studies) with the novel GenoChip microarray, which is specifically designed for anthropological genetics research (Elhaik et al., 2013). This SNP array is an Illumina HD iSelect genotyping bead array with over 130 000 highly informative autosomal and X-chromosomal SNPs ascertained from over 450 worldwide populations analyzed in the 1000 Genomes Project (2010) and the HapMap Project (Altshuler et al., 2010; Durban et al., 2010) and other published studies (Rasmussen et al., 2010, 2011). To avoid any inadvertent medical testing, all SNPs known or suspected to have health or functional associations were filtered out from the GenoChip microarray, and SNPs occurring in coding regions were not selected.

The chip was validated by genotyping over 1000 samples from the 1000 Genomes Project, Family Tree DNA, and Genographic Projects (Elhaik et al., 2013), and served as a worldwide reference database for the project. Initial results indicate a 99.5% concordance between the GenoChip and the 1000 Genomes Project data sets, as well as SNP density of approximately (1/100 000) bases over 92% of the human genome. This array also yields extremely highly resolved maternal (mtDNA) and paternal (Y-chromosome) haplotypes. In addition, when compared to the results from Affymetrix and Illumina microarrays, the GenoChip showed a greater capacity for detecting population substructure (Elhaik et al., 2013). Furthermore, its SNPs overlap with 40–76% of those present in commercial microarrays, making the GenoChip data compatible with those generated with other human genotyping tools.

The GenoChip also contains autosomal SNPs found to be variable in archaic humans such as Neandertals (Green et al., 2006, 2010) and Denisovans (Reich et al., 2012) but which are also present in modern humans (Meyer et al., 2010). The presence of these markers in modern humans suggests their ancestors interbred to some extent with archaic humans as they expanded outside of Africa some 60 000 years ago. Thus, it is possible to estimate the relative percentage of Neandertal and Denisovan markers in participants' genomes by analyzing autosomal SNPs with the GenoChip, hence, determine how 'archaic' they really are.

In addition to this genotyping tool, project researchers have developed a new Geographic Population Structure

Figure 1 North American Regional Center researchers and members of the South Naknek Alutiiq community from Southeast Alaska enjoying a salmon cookout together. Photo by T.G. Schurr.

admixture-based algorithm to explore the ancestry of different human populations. The accuracy and power of this method to infer the biogeography of worldwide individuals down to their country or, in some cases, village, of origin, with autosomal SNP data has recently been demonstrated (Elhaik et al., 2014). These results affirmed the utility of admixture-based methods for reconstructing human biogeography, and raised interesting questions about how population size, genetic diversity, and environmental influences have shaped human population structure.

Public participants are also able to have their DNA analyzed with the GenoChip. Similar to Phase I genotyping, individuals can purchase a cheek swab kit to have their DNA analyzed on the GenoChip at Family Tree DNA (now ancestry by DNA). When the genotyping is completed, participants can access their results at the project Web site through the use of their unique GPID identifiers, as well as opt to include their data in the Genographic database. As a result of their involvement, public participants in this phase of the project will gain a broader understanding of their ancestry in learning what different parts of their genome can tell them about genetic genealogy and inheritance. The inclusion of their data in the project database will also enhance the accuracy of the algorithm used to make proportional ancestry estimates for both indigenous and public participant samples.

Summary

As evident from the preceding discussion, Genographic studies have added substantially to our knowledge of the origin and dispersal of our species. They have expanded our understanding of modern human migration patterns around the globe, the dynamics of human settlement through time, the influence of religion, culture, and language on population genetic diversity, and the evolution of human mitochondrial and Y-chromosome phylogenies. The success of the project has resulted in large part from the involvement of indigenous participants, whose keen interest in learning about their genetic ancestry and collaborative efforts have made this study a mutually enriching experience for researchers and participants alike (**Figure 1**). In addition, the Legacy Fund has supported numerous educational and linguistic initiatives of indigenous communities, thereby helping them sustain their cultural and linguistic heritage. Finally, the knowledge about our deep ancestry that has been contributed by this project demonstrates that we are part of one large, extended family with genetic ties that bind us together, despite our outward biological, cultural, and linguistic differences.

Genomics, Ethical Issues in

Henry T Greely, Center for Law and the Biosciences, Stanford University, CA, USA

Abstract

Improvements in our ability to analyze and understand DNA will have ethical implications for society. The most important issue stem from DNA's ability to predict an individual's future, during his or her life, at birth, as a fetus, as an *in vitro* embryo, or even before conception. There will also be ramifications for health care, in establishing identity, in revealing the past, through genetic manipulation, on ownership and control of genetic material and information, and in cultural understandings of humanness, race, and the roles of nature and nurture.

Genetics, both as a field and as a word, was born in the early twentieth century. The 'new' genetics referred to the vast increase in the power of genetics that followed the increased understanding of the biochemical basis for genetics in deoxyribonucleic acid (DNA). That understanding has made it possible to 'read' the sequence of DNA in organisms, including humans; to discover, in some cases, the physiological significance of that sequence; and to contemplate changing the sequence in order to attain desired ends. These heightened powers have both created new ethical and social concerns and exacerbated older ones.

The first edition of this article was written in 2001. The major development since then has been the growth of 'genomics.' Impressive advances in testing, sequencing, and manipulating DNA mean we can do much more with and to DNA – faster, cheaper, and more accurately – than imagined 13 years ago. Various methods of testing first hundreds, and ultimately millions, of 'single nucleotide markers' in a human genome using 'SNP chips' now cost less than $100, leading to their widespread use in the last 15 years in scientific 'genome-wide association studies' (GWAS) as well as in consumer genomics companies. GWAS still test under a thousandth of the whole human genome, but the first reasonably complete human genome sequence was finished in 2003. It cost about $500 million (depending on the accounting conventions used). In 2014, high-quality whole human genome sequences are routinely available for about $3000 with several firms recently announcing their '$1000 genomes.' These new large-scale capabilities have shifted the focus of scientific interest from individual genes to whole or partial genomes; the scientific language has similarly been moving from 'genetics' to 'genomics,' as will, largely, this article.

At the same time, the major 'nondevelopment' has been the creeping pace of our ability to understand the effects of different DNA sequences. A major question of the last decade has been the mystery of the 'missing heritability' – researchers know, for example, that about 90% of a person's adult height comes from his combination of his parents' genes, but thus far only 10–20 percentage points of that heritability has been attributed to specific DNA sequences. As a result, the consequences of the unexpectedly enhanced sequencing capabilities of genomics have been smaller than we would have imagined.

Concern about implications of the new genetics for human societies grew with scientists' ability to decipher and manipulate DNA. The late 1960s saw discussions of human cloning, followed in the 1970s and early 1980s by safety concerns about recombinant DNA and social concerns about genetic discrimination. When the Human Genome Project was proposed for substantial funding in the United States in the late 1980s, the Project's first director, Dr James Watson, suggested that 5% of the funding be set aside to study the 'ethical, social, and legal implications' (ELSI) of human genetics (Cook-Deegan, 1994). The subsequent financial commitment led to the rapid expansion of 'ELSI' studies across many disciplines and the publication of a vast number of articles and books on these topics. The technical advances brought by genomics have accelerated the timing of some ethical, social, and legal issues, but, because of the slow pace of understanding, neither broadly nor dramatically.

Three general caveats are useful in surveying the resulting discussions of either the 'new' genetics or the 'new' genomics. First, although these new technologies often provide great power, for prediction, or for intervention, they seem unlikely to provide the extent of power often assumed in the writings about their implications. Oftentimes, their predictions will be weak; the percentage of people with a particular set of genetic variations (or 'genotype') who develop a particular trait of condition (or 'phenotype'), a percentage known as 'penetrance,' will often be low. Second, although the technologies are quite novel, their implications almost always have parallels in the social effects of other modern technologies. And third, although much of the discussion of the consequences of genomic technologies has focused on individuals or families, these technologies usually also have implications for broader human groupings. With those caveats in mind, this article will discuss the ethical, social, and legal effects of the new genomics in seven areas: health care, establishing identity, predicting the future, revealing the past, genetic manipulation, ownership and control of genetic material and information, and cultural understandings.

Issues Arising from Medical Successes

Writing on social issues of genomics focuses on the dangers of human genomics misused – lost privacy, genetic discrimination, state-enforced eugenics. It rarely looks at the potential implications of the hoped for uses of genomics to prevent and

 http://dx.doi.org/10.1016/B978-0-08-097086-8.82011-5

treat diseases. The vast sums, both private and public, being spent on research in genomics are not being committed from an altruistic search for knowledge, but in the expectation that the research will bring immense medical benefits. The diseases in question may not be limited to 'genetic diseases'; genomic tools are allowing unprecedented understanding, at the molecular level, of the proper and diseased functioning of human cells and of human pathogens. The most powerful lesson of the first 40 years of the biotechnology industry has been that the human body and its functions are more complicated than expected, but those complications are steadily being tackled with genomic tools. A stream of new treatments, derived from increased knowledge of genomes and their associated proteins, is flowing through research, development, and regulatory approval, not as quickly as one would like, but persistently.

What will happen if these drugs succeed? It is possible that the results might include, among other things, a significant extension of average human life span; an increase in pharmaceutical costs; and changes, up and down, in the demand for various medical services. The social implications could be substantial, on everything from pension plans and political voting blocks to health care systems. Some more focused medical consequences of genomics research, such as individualizing patient therapies as a result of genomic tests (known as 'pharmacogenomics'), or some kinds of proposed genome therapy or tissue replacement will require that treatments be created just for one patient, thus straining the existing mechanisms for drug development, manufacturing, approval, and financing. And any new treatment will raise questions of availability, both within any one country and between countries. Genomics has created a uniquely high expectation of medical progress, which it has used to acquire funding, both public and private. If it comes close to the successes it has promised, these consequences may be raised in dramatic form.

Establishing Identity

Genomics raises four main issues centering around identity: forensic identification, personal identity, family identity, and ethnic identity.

Forensic Identification

By the mid-1990s, the new genetics was leading to major changes in forensic identification. Any tissue from a person that contains DNA can be tested for a pattern of identifying markers, sections of the genome that vary substantially from one person to another. Those markers can be compared with the markers analyzed from human tissue found in connection with a crime (National Research Council, 1992). New and powerful techniques for analyzing DNA mean that samples with only tiny amounts of genetic material can be useful, whether derived from flesh, blood, semen, or even the cells found in saliva. A negative test is very powerful. If the markers are significantly different, the tissues cannot be from the same person (unless the sample was swapped or contaminated or in a very rare case where a single person because of embryonic merger, has some tissues with one genome and some with the genome of a never-born twin). Initially, there was concern that a positive match might not be very compelling because patterns of markers might be relatively common among particular ethnic populations. That could make the odds that a match was a coincidence vanishingly small among the general population but relatively high among people from that particular ethnic group. These fears were largely assuaged through both more information on the distribution of the markers used in forensics and different techniques (National Research Council, 1996).

This forensic use of DNA is not essentially different from the use of fingerprints, blood groups, or dental records. Like those techniques, it has had to prove its effectiveness in a host of judicial cases. And, like the earlier techniques, the DNA itself can never be conclusive. Good defense counsel will always investigate the possibilities of an innocent explanation for the presence of the DNA or for mistakes, contamination, or fraud in the DNA collection and analysis process. Juries and judges might pay more attention to DNA evidence because of the high status and reputation of the science, but that effect should also fade with greater familiarity (and good defense counsel).

The real issues about the forensic use of DNA now concern not the individual case, but the collection and retention of DNA or DNA records for identification purposes. One issue concerns surreptitious collection by the police of DNA from suspects, either through an interaction with them, such as offering them something to drink and getting their DNA from the discarded container, or merely by collecting DNA from items they have had contact with, from cigarette butts to eating utensils. More broadly, many countries or states have created DNA repositories with DNA samples taken from convicted, or even merely accused, criminals. These samples can be used to seek matches in criminal cases or for the identification of human remains. If markers from the samples are analyzed in advance, the results can be put into a database and used to seek 'cold matches' to samples or tissue of unknown origin. These repositories raise two different issues. The first involves their creation. Should samples be accepted only from those who consent or should they be mandatory? If mandatory, what classes of people should be required to provide samples – convicted sex offenders, convicted felons, all those arrested, or the whole population? Litigation on this issue has become increasingly common in the United States, where all states have some form of mandatory DNA repository (*Maryland v. King*). A subtler, but equally important, issue concerns *what* the repository should contain: information on what, and how many, genetic markers? And should the DNA samples from which the profiles were derived be retained or destroyed? The markers currently used for forensic identification, as far as scientists can tell, are not strongly associated with any traits (other than sex) (Kaye and Greely, 2013). If the markers are kept, no information about a person other than identity (and possibly ancestry) can be deduced – nothing about genetically influenced disease susceptibility or other traits. (Using new markers as is currently under serious consideration, could change that.) If samples of whole DNA are kept, however, they can be reanalyzed to confirm that the profile is accurate, which may be important in some contexts, such as some international sharing arrangements. But the samples could also be analyzed for DNA associated with a wide variety of traits. This raises

much broader implications for privacy than a regime where the samples are destroyed after analysis.

Personal Identity

The furor about the possible use of somatic cell nuclear transfer (SCNT) technology to clone not just a sheep, but a human, involves a host of issues (National Bioethics Advisory Commission, 1997). Most of those issues have already been raised as a result of *in vitro* fertilization and other forms of advanced reproductive technologies. The issue unique to cloning is, in essence, a concern about human identity. Would a person with the same genome as another living individual be, in some meaningful sense, a copy of that person?

This and other speculative questions about clones were widely discussed in the aftermath of the announcement in 1997 of the birth of the cloned sheep, Dolly. Concern died down as scientists were consistently unable to produce viable human embryos using SCNT, in spite of fraudulent claims in 2005 by Dr Hwang Woo-suk. In 2013 and 2014, however, new methods did successfully produce apparently viable human embryos and embryonic stem cells from those cloned human embryos. Concern about the birth of human clones has, to some extent, revived.

Monozygotic twins, who account for about 1 in 240 live births around the world, have always shared the same genome. Although their physical similarity is strong, the individual identities, and separate personalities, of monozygotic twins have long been recognized. Cloning by SCNT, if possible in humans, could not produce individuals *more* alike than monozygotic twins. Indeed, the clone and the source of the clone's DNA would most likely be much less alike. They would have spent their first 9 months of development in the wombs of different women, subject to different environmental influences *in utero*. Once born, they would be subjected to different environments, often in very different times. The exact degree to which identical human genotypes produce similar phenotypes would be an interesting research question, in the unlikely event that it could ethically be studied. It seems quite likely that the popular perception of identity would prove grossly exaggerated.

Family Identity

Because genetic variations are inherited, parents and children share half of their genomic variations, as do siblings. Grandparents and grandchildren, as well as first cousins, share, on average, one-fourth of their genomic variations. This fact, along with cheap genomic analysis, makes it possible to use DNA to establish, or refute, close family relationships. This kind of family analysis, using inexpensive SNP chips as well as analysis of variations on the Y chromosome (found only in men and inherited directly from father to son) or the mitochondrial DNA (found in both men and women but inherited only from the mother), has led to the growth of a consumer genetic genealogy industry. At least three major firms each had hundreds of thousands of customers pay to get information about their genetic variations and to look for previously unknown genetic family members. At a more immediate level, genomic analysis can be used to try to find unknown parents, either when a mother (or a government) is trying to identify a genetic father for child support or when a child who was adopted or the product of an egg or sperm donor goes looking for genetic parents. With large enough genomic databases, close family relationships can be picked out easily. Similarly, the police can use genomic analysis to try to determine whether the source of crime scene DNA came from a close genetic relative of someone in a forensic database (Greely et al., 2006). This will become easier if the forensic databases adopt more markers, particularly on the paternally inherited Y chromosome. The ethical implications of using DNA to establish, or to refute, family relationships will vary, depending often on the consent of the family members being found or 'lost.'

Ethnic Identity

Culturally defined human groups – ethnicities or nations – often share more than common cultures, but also share a substantial degree of common ancestry. This genealogical connection implies a genetic connection; particular variations in DNA sequences, or patterns of those variations, will be more common in some populations than in others. This may apply to both common and rare variations. For example, the four ABO blood groups are genetically determined. Each one is found in all (or almost all) of the world's populations, but in different proportions. Other variations in DNA sequence may be found at elevated levels among particular groups and extremely rarely among others (Cavalli-Sforza et al., 1994).

This kind of variation can be used for anthropological research; it could also be used in an effort to define a person's ethnic identity. The latter use would have limited scientific validity; no known DNA variations are found in all members of an ethnic group and in no nonmembers of that group and given the human history of enthusiastic sexual intermixing (and of adoption or conversion), no such variations are likely to be found. Nonetheless, the rise of inexpensive genome-wide testing has led 'biogeographical' tests of an individual's ancestry becoming an important feature of popular genetic genealogy products sold to consumers, who learn that they are, for example, 87% European in origin, 11% Middle Eastern, and 2% sub-Saharan African. There have been reports of governments or ethnic groups using this kind of information for some legal purposes. The ethical implications of the naïve use of such inherently inaccurate methods for defining ethnicity are likely to depend on the circumstances, including the uses made of such definitions and whether they were adopted by the group itself or imposed on it. Any such use, however, would likely have the negative effect of reinforcing the false concept that race and ethnicity have some strong 'genetic' meaning.

Predicting the Future

The most discussed issues arising from the new genetics come from its perceived ability to make predictions about individuals' futures as a result of associations between genetic variations and physical and behavioral traits. These predictions in themselves can have implications for living people; the attempt to make such predictions prenatally can have implications for what people are born. The strength of the predictions will vary

dramatically. Some conditions, such as Huntington's disease, appear to follow inevitably from possession of a particular genetic variation. For other conditions or traits, a person with a particular genetic variation may have a somewhat increased but still small likelihood of having that condition or trait. The ethical significance of such predictions will vary largely based on who uses which predictions for what ends.

Prenatal Selection to Avoid Disease

The new genetics brought the ability to test directly the DNA of the parents and of the embryos and fetuses they conceive; genomics has made such testing increasingly practical. Where the analyzed genotypes are strongly or completely associated with particular phenotypes, whether the children might (when the parents are tested) or would (when the embryos or fetuses were tested) show those traits can often be confidently predicted. This kind of prenatal testing has been used for several decades now in efforts to avoid serious genetic diseases. Early efforts included testing for as sickle cell anemia and for Tay-Sachs disease. In some cases, prospective parents have been tested, in order to alert to them to whether such a disease is a possibility for their children. The prospective parents could use that information to avoid marriage, to avoid having children, or to seek prenatal testing during any pregnancy. This carrier testing, at least when consented to by informed patients, has been relatively uncontroversial; it is now becoming increasingly common, and broad, as commercial firms offer carrier testing for over a hundred genetic disease traits for only a few hundred dollars.

Testing of fetuses is possible only with DNA from the fetus. In the past that DNA was retrieved from cells taken from the amniotic fluid about 16 weeks into the pregnancy through amniocentesis or from the chorionic villi, part of the placenta, at about 10–12 weeks of pregnancy. Both procedures are expensive and increase the risk of a miscarriage. Since late 2011, another method has been available, the so-called 'noninvasive prenatal testing' (NIPT). This makes use of small, broken bits of the fetus's DNA that can be found in the pregnant woman's blood (along with more small bits of her own DNA). It requires only a small blood draw from the pregnant woman and can be done at least as early as the 10th week of pregnancy. By 2014, at least four U.S. companies offered this test for various chromosomal abnormalities, notably trisomy 21, which causes Down syndrome. This test also easily reveals the fetus's sex. It seems likely that, eventually, this relatively inexpensive procedure will be useful to test the fetus for any genomic variation of interest; it has already been used, in a proof of principle experiment, to recreate the fetus's entire genome sequence. Currently only a few percent of pregnancies receive genetic testing; NIPT seems likely to increase that percentage enormously (Greely, 2011).

Whatever the method, after a direct genetic test of the fetus, parents could choose to abort or could prepare themselves better for the birth of a child with the particular genetic condition. Testing of fetuses for genetic conditions has been controversial. Some have opposed it because it often leads to abortion, which they condemn as murder. Some advocates for people with disabilities have been concerned about this kind of testing, especially when followed by abortion, because they believe it implies that the lives of people with those genetic conditions are not worth living. In the United States abortion, at least until the fetus is viable outside the womb, is legal for any reason, so there has been little discussion of outlawing abortion for late onset, low penetrance, or mild genetic conditions; many countries do regulate the reasons for abortion and so face this issue. Even in the United States, a question remains as to whether governments, health care systems, and health care professionals should encourage, discourage, or be neutral on prenatal genetic testing.

A different method may change some of the discussions about prenatal genetic testing. 'Preimplantation genetic diagnosis' makes it possible to test a very young embryo before it is implanted. This procedure can only be done as part of *in vitro* fertilization because the clinicians need to have access to the early stage embryo. One cell is detached from an embryo and the DNA in that cell tested. Based on the results, the parents can decide whether to implant that embryo, or, more realistically, which of several tested embryos to implant. No fetus would be aborted; instead, some embryos would just not be implanted. In the past this procedure has been uncommon; less than 0.1% of annual births in the U.S. follow from it. That percentage may increase. New methods of genomic analysis now mean that rather than testing the embryos for one or two genetic conditions, their whole genomes could be sequenced. Furthermore, within the next few decades the need for egg harvest, the most expensive, unpleasant, and risky aspect of *in vitro* fertilization, may be avoided by using skin or other cells from a woman to make new eggs.

Prenatal Selection for Genetic 'Enhancement'

By eliminating the need to abort in order to choose genetic traits, preimplantation genetic diagnosis also increases the possibility of parents selecting children based on genetic traits that would, the parents believe, 'enhance' their children. The idea of using genetic testing to select 'enhanced' genetic traits for offspring has raised many concerns (Parens, 1998). Some fear that allowing parents to choose, or to believe they can choose, the traits of their children would deny those children their right to 'an open future' not of their parents' choosing. Others worry that the rich will be able to buy genetic advantages for their offspring, denied to those who conceive in the traditional manner. Still others worry that parental selection will lead to a homogenization of the human gene pool, as all parents opt for children with similar traits. On the other hand, some fear that some parents will want to 'enhance' their children by selecting genetic variations that most people would view as *disabilities*. For example, deaf parents might want a deaf child. Finally, some fear that these parental choices could lead to a self-perpetuating genetic caste system. Most of these results require both that genetic variations be identified that strongly predict 'success' and that many parents must be willing to undergo preimplantation genetic diagnosis. Neither is certain.

One might also question whether parents choosing to guide the choices or to enhance the chances of their children through genetics is fundamentally different from parental efforts to do the same through the environment. Rich parents send their children to 'better' schools. Parents with particular interests may push their children from an early age to excel in those

activities – Wolfgang Mozart and Tiger Woods are both successful examples. Arguably, a major goal of parenting is to 'deny' one's children certain unhappy or illegal futures. The argument that enhancement through genotype selection is inherently different or more threatening from other kinds of enhancement is not an obvious one.

Sex selection is a special case of 'genetic enhancement,' though one that can be done through sonography as well as genetic testing. In some countries, prenatal sex selection by abortion is common with female fetuses being aborted much more frequently than males. This seems likely to produce striking imbalances in the sex ratio in those countries, which may have broad social consequences. It also, some argue, reinforces the subordinate position of women in those cultures. Easier genetic testing, through NIPT or greater use of preimplantation genetic diagnosis could increase the use of sex selection (Hvistendahl).

State-Sponsored Prenatal Genetic Selection

The discussion thus far has focused on parental choices about their children's genetic makeup, but parents need not make those decisions. Governments have intervened to prevent people with 'inferior' genes from having children; such eugenics laws could come again in more precise forms. 'Eugenics' is discussed in detail in other articles and will not be reviewed here except to note two things. First, state-sponsored eugenics measures do not have to be compulsory; state actions to encourage prenatal genetic selection can also be, in a sense, eugenics. Second, the ethics of government-sponsored eugenics depends on striking a balance between government public health powers and individual procreative liberty that remains in debate.

Postnatal Genetic Testing

The possibilities of genetic testing do not end at birth. Genetic tests can help diagnose diseases or predict future disease risks. Like all medical interventions, their value depends on them being used appropriately (President's Commission, 1983; Institute of Medicine, 1993). Postnatal genetic tests provide information that can lead to a medically useful intervention, that can help the patient make life plans, and that might just satisfy a patient's desire to know her future. Genetic testing also has costs. Test results may pose psychological problems for those tested or affect the patient's relationships with family members. They may have implications for the patient's dealings with the broader society, through employment or insurance discrimination. Where tests, genetic, or otherwise, do not have powerful implications for medical intervention, the strong influence of the individual's personality and circumstances on the value of testing argues a for particularly good process of informed consent, especially when the patient's understanding of the links between genetic variations and disease may be weak. Testing children is particularly ethically suspect unless there are useful medical interventions that need to be done during childhood. Otherwise, the benefits of testing for children could be put off until they reached adulthood and were able to make their own informed decision on testing. On the other hand, when there are good early interventions, testing for children becomes more important. Most jurisdictions require, or strongly encourage, neonatal genetic testing for diseases, such as phenylketonuria, where early diagnosis can lead to interventions with enormous benefits.

Improvements in DNA analysis offer the realistic possibility of whole genome sequencing as an affordable method of genetic testing, for diagnosis or for screening. Instead of looking for just one, or a handful, of genetic conditions, whole genome sequencing offers the possibility of seeing all genomic variations. Many issues remain concerning both the analytic validity of evolving whole genome sequencing techniques – how accurately they actually analyze the DNA sequence – and, even more, the clinical validity of interpretation of whole genome sequencing – how accurately medical conclusions can be drawn from them. Other problems concern what findings to return to patients, particularly, if those problems were not the reason for the test. And determining how to provide patients with meaningful information on hundreds or thousands of genomic risks (or advantages) will prove challenging (Ormond et al., 2010). All of these issues will be particularly troubling with respect to tests of children, especially if the currently mandatory neonatal genetic testing is replaced with whole genome sequencing.

Of course, many medical tests predict higher or lower disease risks. The diagnosis of a disease, whether through genetic or nongenetic methods, can trigger many of the same costs as prediction. Genetic diseases do implicate family members to an unusual extent, but shared environments or diets can also put family members at shared risk.

Genetic Discrimination

Great concern has been expressed about the possible uses of genetic tests to discriminate against people based on genetically predicted susceptibilities. Employment, life insurance, and, in the United States, health insurance are the fields where genetic discrimination seems to be most feared. The likelihood of genetic discrimination depends on two different sets of factors: the strength of the prediction possible from genetic information and the social structure governing the relevant fields.

For someone with the allele that leads inevitably to the fatal condition, Huntington's disease, genetic prediction is quite powerful. Fortunately, such powerful genetic predictions are rare; it is not clear that employers or insurers would find significant an increased risk of diabetes from 10 to 15%. Similarly, discrimination in health insurance has been mainly a concern in the United States; all other rich countries guarantee health coverage to all, or almost all, of their residents, a direction in which the United States is moving. Even in the United States, the great majority of Americans with health insurance obtain it through methods that are not directly susceptible to genetic discrimination. Medicare, Medicaid, and employer-provided health insurance are not medically underwritten – they must accept everyone eligible without using any medical exclusions. They cover about 90% of Americans with health coverage. There is little good evidence that genetic discrimination in employment or insurance exists in the United States, although there is clear evidence of public fear of such discrimination.

Until 2008, no federal law banned genetic discrimination in insurance or in employment, although many state laws banned one or both. In 2008, the United States adopted the Genetic Information Non-Discrimination Act, known as GINA, which largely banned the use of genetic information in employment and in health insurance. GINA does not cover discrimination in life insurance, disability insurance, or long-term care insurance. The United Kingdom, where the National Health Service makes private health insurance of limited importance, has set up a regulatory authority to pass on whether or not life insurers may require tests for particular genetic conditions; the body recently approved the use in life insurance of predictive genetic testing for Huntington's disease. How well statutes limiting genetic discrimination will work remains unclear, although GINA has not yet been expensive or difficult to enforce. If some of the statutes banning genetic discrimination are able to function with relatively low costs, one might justify them on the pragmatic ground that they increase the research on and clinical use of human genetics by reducing public fears, whether or not those fears are justified (Greely, 2001).

Prediction of Behavioral Traits

The successes of the new genetics have largely been in associating genetic variations with physical traits or conditions. Much of the public interest in genetics and genomics, though, seems to lie in its possible to use to predict human behavioral traits, such as intelligence, sexual orientation, violence, or mental illness. Some human behavioral traits have been linked to genetic variations, including some forms of intellectual disability. For the most part, though, efforts to link genetic variations with human behavioral variations have, thus far, had little success and even the successes have been controversial. At this point, it is not clear to what extent genetic variations will prove able to lead to strong behavioral predictions. If such predictions were possible, the ethical implications could be substantial (Carson and Rothstein, 1999).

Strong links between genetic variations and behavior might undermine notions of personal responsibility for the involved behaviors. At the broadest level, they could affect society's view of the extent of individual free will. More narrowly, they could affect the society's view of, for example, 'genetically determined' criminal behavior or sexual orientation, although whether the result would be more or less tolerance for the behavior is not clear. These kinds of genetic predictions could also lead to interventions in individual's lives – people predicted to be likely to act violently might be put into custody before they committed any offense. The successful association of behaviors perceived as important with genetic variations would boost the interest of both parents and governments in prenatal genetic selection.

Societies make predictions about future individual behavior in many ways, from aptitude tests to past records. Except for its prenatal uses, it is not clear that doing a genetic test to determine, for example, musical ability, would offer any advantages over doing a direct test of such ability. Genetic tests would have an advantage only when the genetic prediction is strong and the behavior is not easily observed directly. At this point, it is not clear that many strong associations between human behavior and genomic variations will be discovered; the problem of 'missing heritability' has been particularly great with behavioral traits. The real ethical issues with behavioral genetics may turn out to be preventing misuse by cultures that believe in its reality even in the face of uncertain science.

Uncovering the Past

DNA can reveal aspects of the past as well as of the present. In some cases, DNA, by providing another line of evidence, can raise in new contexts issues of the privacy of historical figures in matters such as Thomas Jefferson's relationship with his slave, Sally Hemmings, or whether Abraham Lincoln had Marfan's syndrome. Other historical uses of DNA raise broader questions.

Individual Ancestry

Genetic variations can be used in a straightforward way to establish close biological relationships. Blood groups or isoforms of particular proteins have long been able to provide such information; direct DNA testing can increase the accuracy of such determinations. The ethical implications of such paternity or maternity testing vary according to its use. If done with the full consent of all relevant parties, it seems unproblematic. If done without consent of one of the parties, it might be justified, as perhaps in establishing child support obligations, but would require some consideration. One problem arises where genetic testing done for some other reason, such as attempting a diagnosis of a disorder of possibly genetic origin in a child, reveals unsought information about parentage, such as 'false paternity,' that might be unwelcome and even dangerous. Another problem could be its use by children to find sperm or egg donors who were promised anonymity.

Group Histories

Analysis of patterns of genetic variation among different human populations can reveal how closely related two populations are. This information then becomes some evidence about human history and migrations. It is not conclusive evidence, but would join with linguistic, archaeological, anthropological, historical, and other sources to improve understanding of the human past (Cavalli-Sforza et al., 1994). The information may not always be welcome. It may contradict a population's own beliefs about its history. In some situations, that information alone might destabilize or disrupt the entire culture. It could also have modern political implications where ancestral origins, and the length of time in possession of particular territories, could affect land disputes. Whether a historical researcher has ethical obligations to avoid doing research that could provoke such consequences is unclear. Similarly unclear is whether there is an ethical obligation to seek the informed consent of the entire group to such genetic research that might have consequences for the group (Greely, 1997). Such consent has not generally been thought necessary for other historical investigations affecting contemporary peoples; some might argue that 'genetic history' is different, either because of the nature of the materials being used or the different degree of certainty perceived for such 'scientific'

evidence. Somewhat similar issues arise about the necessity of obtaining permission for genetic analysis of human remains.

Manipulating Genes

The new genetics made it possible not just to read an organism's genes but to change them. The newer genomics is greatly enhancing that ability, creating additional concerns.

Somatic Cell Gene Therapy

Somatic cell gene therapy involves the placement of a human gene into a living person's somatic cells – cells that do not produce the eggs and sperm that in turn produce the next generation. Somatic cell gene therapy would aim to cure a disease only in the patient, not in the patient's descendants. It was initially conceived as introducing a properly functioning copy of a gene into a person who had a genetic disease as a result of inheriting only improperly functioning copies. Different types of somatic cell gene therapy have since been investigated for the treatment of diseases that are not primarily caused by inherited genes, such as AIDS and most kinds of cancer. Over one thousand clinical trials of somatic cell gene therapy have taken place; very few have, thus far, shown any success, although by 2014, good results were beginning to accumulate.

The genetic aspects of somatic cell gene therapy have been largely uncontroversial. In essence, gene therapy is merely another drug delivery system, a different way to get a normal human protein to the right place in the body. Somatic cell gene therapy therefore stands in the same position as most experimental therapies. Like such therapies, it has prompted concerns that desperate patients are not truly giving informed consent and that the possible benefits of the treatment are exaggerated. Gene therapy may face the latter problem to a greater extent than most experimental treatments because of the exaggerated public view of the power of anything genetic.

Germ Line Gene Therapy

Germ line gene therapy has been much more controversial (Nelson, 2000). In its usual form, it would introduce 'normal' human genes into the eggs or sperm of parents, or into the fertilized egg or early embryo of the offspring. The goal would be to change the eventual child's genetic inheritance. This could be done in order to avoid a genetic disease or in order to introduce an 'enhancing' genetic variation. No one has tried human germ line gene therapy in its classic sense; indeed, there has been an informal moratorium in the scientific community on trying such experiments in humans. Both its feasibility and its value are unclear.

New genes have been successfully introduced into the germ lines of other mammals, but with low efficiency. At the same time preimplantation genetic diagnosis allows parents to choose embryos based on their genetic variations, as long as the parents themselves produced the desired variations. If not, donated eggs or sperm would likely be a much safer and easier way to introduce the desired genes than germ line cell gene therapy; ultimately, somatic cell gene therapy might provide another way for parents to change their offspring's genetic variations.

One kind of germ line gene therapy is plausible, has been tried, and is currently being debated: mitochondrial transfer. The mitochondria, organelles found in all eukaryotic cells, including human cells, have their own very small genome. In humans, mitochondria, and hence the mitochondrial genome, are inherited only from a child's mother. If the mother's mitochondrial genome has variations that cause disease, all of her children will carry the same pathogenic DNA. This can be avoided by combining the nucleus of an egg from the woman who wants children with mitochondria from a woman with a healthy mitochondrial genome. At least one *in vitro* fertilization clinic in the United States tried this procedure in the late 1990s and early 2000s, but abandoned it when the Food and Drug Administration asserted jurisdiction over the procedure. In 2014, researchers have sought approval from authorities in both the United Kingdom and the United States to resume experiments with this mitochondrial transfer procedure, which would allow afflicted women to have children without their disease, but would change the genomes of all cells of the children, including their egg and sperm – though only the female children could pass on their mitochondrial DNA. These efforts have been quite controversial, raising concerns about children with 'three parents.'

Chimeras

The manipulation of genes permits the creation of 'chimeras,' creatures that are genetically a mix of two species, including organisms that could not possibly mate. In agriculture, this mixing of genes from very different organisms has been perceived by many as unethical and potentially dangerous. Unless one takes a strong view of the reality and sanctity of sharp lines between species, it is hard to develop a strong ethical argument against such mixes. On the other hand, one might argue that a gene in the new setting of a different species might develop different and possibly harmful functions than in its home species.

Chimeras involving human genes could provoke greater concern. Intentionally moving nonhuman genes into humans could be seen as lessening the humanity of the recipient; moving human genes into nonhumans could be seen as investing nonhumans with some aspects of humanity. The former has not been attempted; the latter, however, is routine. Most of the products of the biotechnology industry, including insulin, erythropoietin, and human growth hormone, are made by creatures that are genetically partially human and partially nonhuman. Human genes are transferred into useful host cells such as yeast, which then produce large amounts of the human protein for which the gene codes. Of course, an organism with 5300 yeast genes and one human gene does not seem very human; to be concerned about this kind of chimera would require a very strong belief in the essentially human, or sacred, nature of any human DNA sequence. Moving more human genes or moving human genes into more closely related organisms, such as chimpanzees, could provoke more serious concern about blurring the definition of humanity.

Artificial Genes or Genomes

It is possible for scientists to create 'new' genes, not found in any existing species, that would create new or modified proteins. One branch of the biotechnology industry specializes in such efforts, named 'directed evolution.' The technology takes related genes from different species, recombines them or makes mutations in them, and then examines how well the resulting protein functions. Similarly, scientists could construct, piece by piece, a novel genome. Placed inside a cell, it might be able to generate a new living organism. One research team has already synthesized the genome of one bacterium, inserted it into a related bacterium, and the resulting organism lived, reproduced, and seemed ultimately indistinguishable from the first bacterium. In 2014, another group synthesized, with a few changes, chromosome 3 of the 16 in a common yeast, used it to replace a natural copy of chromosome 3, and produced a viable yeast cell. New methods of synthesizing DNA, coupled with new methods for targeted replacement of specific existing DNA with synthesized DNA (particularly a method called CRISPR) greatly increase the possibilities of genomic editing. These techniques are unlikely to be used soon in humans, where the safety consequences are potentially enormous, but may well be used to transform bacteria, plants, and nonhuman animals. Recreating recently extinct species may be possible; creating quite new species – from algae for biofuels to unicorns for entertainment – is also plausible.

The safety of making new genes, and hence new proteins, or new genomes, and hence new organisms, is an obvious concern. The deeper concern would be whether humanity should 'play God' by intentionally creating such new entities. Of course, since the invention of agriculture, humans have created new kinds of organisms by cross-breeding between species and by selective breeding within species. New genes are created whenever a gene is mutated, which is sometimes a conscious step in experiments with nonhuman organisms. The speculative possibilities outlined here are more significant, and less accidental, interventions. It is not clear whether that makes them ethically different.

Ownership and Control

Research

Rules governing the conduct of human genetics research control the research subject's genetic materials and information. These rules generally require the informed consent of the subject to the research. Research subjects, however, rarely have any control over the subsequent uses of materials or information derived from them (Greely, 2007). The California Supreme Court decision in *Moore v. Regents of the University of California* (1990) ruled that the plaintiff could not assert a property interest in a cell line derived from cells taken from his body, although it allowed him to try to prove that the physician–scientist had not gotten his informed consent. There have been few court decisions on this point, but current practice generally follows *Moore* and gives research subjects no control over who can use their previously collected genetic materials and information, for what purposes, or for how long. Current practices also discourage any sharing of financial benefits of the research with the subjects on the theory that the hope of such benefits could be an 'undue inducement' to them to take part in the research.

Since the late 1990s, the improved ability to analyze DNA has led a new approach to human genomics research. This associational research seeks to find weak connections between genetic variations and disease by searching for correlations between the genotypic and phenotypic data of large groups of people. Originally, it was undertaken using SNPs, increasingly it can be done with whole exome or whole genome sequence data. This kind of research requires the creation of a resource made up of health records and DNA samples (which are then analyzed for their genotypes) of hundreds of thousands of people. These resources would be too expensive to be created for the study of one kind of illness. Instead, the resources would contain complete medical information and be available to test a wide range of hypotheses. Iceland provided the first large example of this kind of 'genotype/phenotype resource' or biobank, when the government gave a private firm, deCODE Genetics, the license to create a health records database with clinical, medical, and genetic information on all 275 000 residents of the country.

For the genealogical information and health records of Icelanders, the Icelandic legislation provided that consent was presumed; unless an Icelander returned a government form 'opting out' of the database, their records would be included. Explicit consent was required for the inclusion of a person's DNA information. The Icelandic plan raised numerous ethical concerns, including the use of presumed consent, the absence of discussion of the risks and benefits of specific research done on the resource, the degree that privacy would be protected, the access (if any) of other researchers to the company's data, the propriety of having a for profit company control this information, and the financial fairness of the agreements between Iceland and deCODE (Greely, 2000). The Iceland/deCODE plan ultimately foundered, largely for financial reasons, but other countries have created similar biobanks, notably the United Kingdom with its UK Biobank made up of samples and data from 500,000 volunteers with current plans to sequence the whole genomes of at least 100,000 of the participants. These biobanks raise similar issues. Soon, however, even bigger 'virtual' biobanks are likely to exist. Once a substantial number of patients have their whole genomes sequenced for medical purposes, all of their health information and their entire genome sequence will be stored in their electronic medical records. This will be an irresistible and potentially population-wide source of data for researchers; what kinds of consent or control will be required from the patients is unclear.

Patents

No single case unequivocally announced that genes, or human genes, could be patented, but when the U.S. Supreme Court, in *Diamond v. Chakrabarty*, approved a patent on a genetically altered bacterium, it started a continuing debate over the patenting and genetics (*Diamond v. Chakrabarty*, 1980). To many patent lawyers, DNA is just another organic molecule. Patenting of forms or parts of it seems them to fall within long-established principles concerning the composition of matter patents on molecules not found in pure or refined form in

nature (Eisenberg, 1990). Others objected to some or all gene patents on a variety of grounds. Those objections can be put into two categories: fundamental and technical.

Some people have fundamental objections to patents on genes, on human genes, or on genetically modified life forms. One set of objections, focusing on genes, contends that they are 'discoveries,' not 'inventions,' and so should not be patented. Others point out that genes were made by God, nature, or evolution – in any event, something other than those filing the patent claims – and should not be allowable as intellectual property. Another objection is that human genes are the common heritage of mankind and should not be 'owned' by anyone but should be held in common. Still others oppose gene patents as part of broader opposition to biotechnology; forbid genetic patents and the technology would, at least according to the industry, be slowed. Proponents of gene patents put forward answers to each of these objections; throughout the industrialized world, the proponents won. Patents on genes, human genes, and to a somewhat lesser extent genetically modified life forms were commonly allowed in the United States, Europe, and Japan. It is worth noting, though, that most patents expire 20 years from the date of application. The first wave of gene patents has already expired; presumably all patents on human genes will have expired by 2021, 20 years from the publication of a draft of 'the human genome.'

This broad picture was upset when the United States Supreme Court ruled in *Association for Molecular Pathology v. Myriad Genetics* (*Association for Molecular Pathology v. Myriad Genetics*, 2013) that naturally occurring genomic sequences could not be patented as 'compositions of matter' because they were 'products of nature.' The Court did say that humanly modified genomic sequences, such as 'complementary DNA,' could be patented. The *Myriad* case did not deal with patents on uses of DNA, although a slightly earlier Supreme Court decision, *Mayo Collaborative Services v. Prometheus Laboratories, Inc.* (*Mayo Collaborative Services v. Prometheus Laboratories, Inc.*, 2012) has limited the power of patents on genetic tests. The Court held that a test that compared the level of a molecule in a patient's blood to a known set of ranges and made dosing decisions as a result could not be patented because it was a 'law of nature.' That doctrine has already been used to invalidate patents on the process of comparing the sequence of a patient's BRCA 1 and BRCA 2 genes with known 'safe' and 'dangerous' sequences for the purpose of assessing cancer risk. The ultimate results of these Supreme Court decisions on the patentability of genes, genomes, and genomic technologies remain unclear.

Privacy

Protecting the privacy of genetic information is one way to control its use (Annas et al., 1995; Rothstein, 1997). But such 'genetic privacy' legislation raises its own set of problems.

The first problem is definitional – what is the 'genetic information' that should be protected? Information about a person's genetic variations can come from DNA tests, from other biochemical tests, from a naked eye examination, or from family history. A narrow definition, focusing on the results of 'genetic tests,' would miss such powerful information as the 50% chance that the child or sibling of a Huntington's disease patient carries the Huntington's allele. A broad definition, covering everything from which an inference can be drawn about a person's genotype, would cover almost all medical information. A very high cholesterol level is strong evidence that a person carries two alleles for familial hypercholesteremia. An average or low level is strong evidence that he or she does not. GINA deals with this problem, but mostly in the context of forbidding the use of genetic information to discriminate against people in employment or health insurance; not as a general privacy protection of such information.

If almost all medical information leads to inferences about genotypes, it may not make sense to try to protect 'genetic information' separately from medical information. And it may not be possible to 'protect' a person's medical information from the many institutions that have legitimate uses for it, including physicians; hospitals; and those employers, insurers, and governments that pay health care bills. At the same time, the passage of legislation expressly to protect 'genetic' information sends the public the inaccurate message that genetic information is always much more powerful and important than other medical information. Legislation to protect genetic privacy has been introduced in the United States Congress but has not been passed. Several states have passed such legislation, but it is too early to tell how effective that legislation will prove.

Cultural Consequences

The most far-reaching, but hard to predict, ethical implications of genomics may lie in its effects on society's beliefs. Three areas stand out.

First, genomics demonstrates, in a very powerful way, that all life on earth is related. Over one-third of the genes found in the single-celled brewer's yeast have recognizable relatives in the human genome. Some stretches of DNA appear in close to identical form between humans, mice, and fruit flies. Indeed, there appear to be few specifically 'human genes' but many human variants of genes shared by all mammals, vertebrates, multicellular creatures, or life forms generally. Darwin's thesis that all earthly life is related by descent from a common ancestor can be seen in these similarities in DNA. It is unclear what cultural significance, if any, this will have. It could not promote vegetarianism, because genomics shows that carrots and corn, like sheep and cattle, are our relatives. It might, however, promote greater respect for nonhuman life.

Second, the new genetics shows that all humans are closely related. Humans are all cousins. Our DNA differs, on average, at one spot in 1000. In the regions of the genome that code for protein, the differences are one base pair in 10 000. Humans from opposite ends of the earth are far more similar to each other genetically than are chimpanzees from the same band. Genetic theories were used to provide support for a 'scientific' racism in the first part of the twentieth century. Genomics should provide evidence against such racism.

Third, genetics may shift the balance in the cultural debate between nature and nurture as the source of human characteristics (Degler, 1991). Dr James Watson, codiscoverer of the structure of DNA, was famously quoted as saying "We used to think that our fate was in the stars. Now we know that our fate

lies in our genes." In a debate that has raged for centuries, DNA may appear to be proof that individuals are powerfully shaped by forces beyond their control. In fact, genomics paints a more complicated picture. Genes play a role in the development of many traits or diseases, but the environment or luck may also be essential. The general population seems to hold a much stronger belief in the power of genes. For that reason, genomics could end up promoting a more closed and fatalistic view of human life and abilities than either current society holds or science would support (Nelkin and Lindée, 1995). That reaction may prove to be the most significant ethical challenge of the new genetics.

Genotype and Phenotype

Abstract

The distinction between genotype and phenotype is the distinction between the state of genes of an organism (genotype) and the developmental manifestation of those genes in the physiology, morphology and behavior of the organism (phenotype). The phenotype is a consequence of a unique interaction between the genes of the organism and the sequence of environments in which the organism's development takes place. In addition, random events at the level of cell metabolism and cell division cause differences in phenotype between organisms that are identical genetically and have undergone the same developmental environments.

The fundamental distinction between genotype and phenotype was first introduced into biology by Wilhelm Johannsen in 1911 to make explicit a distinction that was implicit in Mendel's explanation of heredity, and which marked it off from previous theories of inheritance. Mendel found that when he crossed two pure-breeding varieties of garden pea, the first generation of hybrid offspring were indistinguishable from one of the two parental strains, but if these hybrids were crossed with each other, both of the original types appeared in the offspring of these hybrids. So, for example, a pure bred red-flowered crossed with a pure bred white-flowered form produced all red-flowered plants, but these, when interbred with each other produced both red and white-flowered plants.

In order to explain this extraordinary result, Mendel postulated the existence of internal, unseen 'factors' contributed by each parent to the offspring, factors that were causal determinants of the outward appearance of the plants, but whose nature was unaffected by their passage from one generation to the next. So, pure bred white-flowered plants had two white 'factors' one contributed by the pollen and one by the egg of their male and female parents, while pure bred red-flowered plants had received two red 'factors' from their two parents. The hybrids of red-flowered and white flowered forms would then contain one red and one white 'factor,' yet these plants were indistinguishable in appearance from a parent that had two red 'factors.' There was then a fundamental distinction between the state of the internal causal 'factors' and the outward state of the plant that carried them. Moreover, to explain the reappearance in the next generation of some white-flowered plants, Mendel had to suppose that the temporary coexistence of red and white 'factors' in the hybrids had no effect on their nature, but that they could be passed on uncontaminated to the offspring of the hybrids. An offspring of the hybrids that happened to contain two white 'factors' was then white like its white grandparent.

This scheme of explanation makes a radical separation between the internal factors that behave according to one set of physical relations in their passage between generations, the laws of *heredity*, and the external appearance of the organism that results from a different set of physiological relations which determine the consequences to the organism of carrying those factors, the laws of *development*. This distinction between the phenomenon of heredity and the phenomenon of development which we usually associate with August Weissman's separation of the germplasm from the somatoplasm had already been made by Mendel 20 years earlier. Earlier theories of heredity had not made such a separation of inner factors from outward manifestation and had been posed as the problem of the inheritance of the organism's characters themselves. It was Mendel's realization that characters are not inherited, they develop. In Johanssen's terminology the description of an organism's internal factors that were passed on to it in the gametes from its parents is a specification of the organism's *genotype*, while the description of the total physical and behavioral state of the organism is a specification of its *phenotype*.

Description of Genotypes and Phenotypes

As a result of the discoveries in molecular and cellular biology since Johanssen's time genotypic and phenotypic descriptions have become more concrete, more detailed and greatly amplified in their scope. Originally genotypes had no independent physical descriptors but were distinguished from each other entirely on the basis of the external phenotypic manifestations and the patterns of similarity in phenotypes of related individuals. 'Genes' were simply abstract placeholders of unknown physical composition, inferred entities that could be characterized only by their phenotypic effects.

The modern identification of DNA as the physical material that behaves in heredity in the manner inferred for Mendel's mysterious 'factors' has allowed a precise physical description of the genotype of an organism. It is the complete spatially-ordered sequence of the four alternative nucleotide bases, adenine, cytosine, guanine and thymine contained in the DNA of the organism's cells. In its most complete form this genotypic description includes not only the DNA in the nucleus of the cell but in certain cellular organelles such as mitochondria or chloroplasts that carry the DNA that is related to their physiological function and that is passed across generational lines. Phenotypic description has also been greatly amplified beyond the external characteristics of individuals. It now includes the gross structure of the various cells of the organism, the physico-chemical description of the various

molecules within cells, including their shape and intra-cellular localization, and the network of biochemical reactions in which these molecules participate.

The concepts of phenotype and genotype require a distinction between *types* and *tokens*. Phenotype and genotype are, as the words indicate, types, sets of which individual organisms are members, sets delineated by the complete descriptors of those organisms. Any individual member of these type sets is a token of the type. In addition it is necessary to distinguish the descriptors of organisms from the physical object or behavior that is being described. The concepts phenotype and genotype refer to the descriptors. The physical objects that are being described are the *phenome* and *genome* of an organism, the actual physical material or behavior of some particular individual and its actual DNA molecules. If we take the definitions literally, then no two organisms belong to the same phenotype because there is always some physical difference in morphology, physiology and behavior between any two organisms, even between identical twins, cloned individuals, or cells that result from asexual reproduction. Moreover, except for the results of twinning, cloning or vegetative reproduction, no two individuals belong to the same genotype, as the process of mutation guarantees some variation in their DNA between any two individuals.

The rate of mutation per nucleotide per cell division is of the order of one in a billion, so for mammals, with over a billion nucleotides of DNA making up their genes, even identical twins are likely to have some small difference in total genotype. There is, in addition, an ambiguity in the assignment of an individual to a genotype because mutations occur during the millions of cell divisions that occur in development, so that all cells in the body do not have identical DNA.

In practice phenotypic and genotypic descriptions are not total but partial, referring to some aspect of the genome and phenome that are of particular interest, while ignoring the rest. The partial phenotypic and genotypic descriptions are partial in two senses. First, only some aspect of the morphology or function of the organism is characterized; say the rate of enzymatic splitting of alcohol, a phenotype, and the DNA sequences that code for the enzyme proteins involved in the reaction, a genotype. Second, a decision must be made about the collection of actual partial phenotypes and genotypes that will be regarded as indistinguishable. At the phenotypic level, given the actual variation in enzymatic rates from individual to individual and from time to time, what range of rates will be regarded as belonging to the same phenotypic class? For any phenotypic variable that is continuous, some boundaries of distinguishable phenotypic classes must be laid down in order to make a mapping between phenotype and genotype because genotypes, by their nature, are discrete classes.

The problem of aggregation exists at the genotypic level as well. The relation of DNA differences to differences in the amino acid sequence of a protein is not one-to-one. Because the DNA triplet code is redundant, substitutions of nucleotides in the third position of the triplet often do not change the amino acid that is specified, so for some purposes many different alternative DNA sequences of a gene count as the same genotype. On the other hand, nucleotide substitutions that do not affect the amino acid sequence of a protein may affect the rate of synthesis of that protein and so may, for some questions, be counted as belonging to different genotypes.

The decision about which aspects of total phenotype and genotype are relevant in creating genotypic and phenotypic classes is a deep question of biology that is largely ignored because everything cannot be considered at once. Sometimes biologists act as if the rest of the organism really were constant, sometimes they recognize the variation but claim that it is causally irrelevant to the phenomenon of interest and sometimes they admit its causal relevance but claim that the variation can be treated as background experimental noise that can be averaged out by repeated observations on a large class of individuals. These decisions are usually made either for the sake of observational convenience without a coherent rationale or from a commitment to a reductionist view of the organism that asserts that an understanding of the whole system can be obtained by breaking it down into 'obvious' small components to be studied in isolation.

Relationship Between Genotype and Phenotype

It is clearly true that organisms do indeed consist of a collection of quasi-independent genotypic and phenotypic subsystems, within which there are strong interactions and between which there are very weak interactions. But the boundaries of these genetic and phenotypic subsystems can only be found by actual experiment and differ from function to function. The hand and eye are, as far as is known, developmentally independent systems for which different gene combinations are relevant during embryogenesis, but handeye coordination is essential for reaching out and picking up observed objects and so cannot be regarded as phenotypically or genotypically independent in considering this elementary behavior.

The problem for genetics and development is how the genotypic and phenotypic spaces map into each other. It is now certain that Weissman was correct in claiming that the genotype-phenotype mapping is causally asymmetrical. Genotypic differences may cause phenotypic differences during the process of development, but there is no material pathway by which changes in the phenome can result in related changes in the genome. There is no biological inheritance of acquired characters. This causal asymmetry sets the program for developmental, physiological and behavioral genetics which is to discover the mechanisms by which the reading of DNA by the cell machinery is causally efficacious in influencing the phenotypic state of the organism. This is the problem of making the forward mapping of genotype on to phenotype.

There remains, then, the problem of the backward mapping, how the causal knowledge of epigenetic processes can be used to infer the genotype, given the phenotype. Even if a knowledge of the genotype gave perfect information about the phenotype, the inverse would not be true, as discovered by Mendel. The phenomenon of dominance alone makes it impossible to distinguish between heterozygotes and homozygotes from phenotypic information at an arbitrary level. In addition, the same phenotype may appear as a result of changes at different locations in the DNA. There are, for example, more than 200 different nucleotide substitutions known in the genes coding for blood-clotting proteins, any one of which leads to hemophilia. The major difficulty of mapping between genotypes and

Figure 1 The growth of cloned plants of *Achillea* at three different elevations. The ordinate shows final the plant height and the abscissa the elevation. Each connected line is the pattern of growth for a different cloned genotype. Data of Clausen, J.D., Keck, D., Hiesey, W.W., 1958. Experimental Studies on the Nature of Species, vol. 3. Environmental Responses of Climatic Races of Achillea. Carnegie Institution of Washington Publication No. 581.

phenotypes is, however, in the forward direction. The complete DNA sequence of an organism does not contain the information necessary to specify that organism.

Genotype, Phenotype, and Environment

First, the outcome of development and the ongoing functioning of an individual is the consequence of a unique interaction between the molecules contained in the fertilized egg, including the DNA, and the sequence of environments in which development occurs. Figure 1 shows the result of a cloning experiment in a plant, *Achillea*, grown at three different elevations in the Sierra Nevada. Immature plants were sampled from nature, each plant was cut into three pieces, and one piece was replanted at each of the three elevations. The figure shows the height to which the pieces grew in the different environments, each line connecting the three genotypically identical pieces in the three environments. A line, giving the phenotype of a given genotype as a function of different environments is a *norm of reaction*. The norms of reaction in this case show that there is no genotype with unconditionally better growth and, in fact, there is no way to predict the order of growth of the different genotypes in one environment from their order of growth in another environment. Thus, the phenotype is not only contingent on the environment but in an unpredictable and irregular way.

Such irregular and particularistic relations between genotype and phenotype in different environments is characteristic of norms of reaction whenever they have been measured for morphological and behavioral characteristics in experimentally accessible organisms. There are, of course, extreme exceptions; genotypes that result in the same phenotype in any environment and environments that are in no way contingent on genotypes for their effect. Eye color variation among humans is entirely a consequence of genotypic differences, uninfluenced by environment, while regional and social class differences in the phonemic structure of speech have no influence of genetic differences. Moreover, major differences between species are a consequence of genetic differences that are manifest in all environments. There is no environment in which a gorilla could learn to write this article. Within species, however, the vast majority of phenotypic variations in morphology, physiology, and behavior are a consequence of particular contingent relations between genotype and phenotype.

Developmental Noise

Second, even a complete specification of the genotype and the environment is insufficient to specify the organism. All cells contain a very small number of copies of biologically active molecules, spatially segregated within the cell, so that the number of various reactions per unit time vary greatly from cell to cell and time to time. Moreover, when cells divide they do not distribute the molecules exactly evenly, except for DNA which has a special machinery for guaranteeing its equal distribution. The consequence of these small molecular numbers is that there is random variation from cell to cell in time to the next cell division, in cell size, in cell shape and in the movements of cells during development. These random events, random at the level of thermal and quantum chemical molecular states, can have considerable effect on the formation and behavior of the whole organism. (Goss and Pecoud, 1998)

So-called 'bilateral symmetries' are not, in fact, symmetrical but vary between sides in an irregular way from individual to individual. The fingerprints on the left hand are not identical, although similar to, those on the right. Such *random developmental noise* is a nontrivial source of variation in phenotype. During the development of the central nervous system of a multicellular organism, superimposed on the major regular patterns of neuronal connection are random variations in the growth and connections of specific neuronal pathways, even in organisms like the roundworm *Caenorhabditis* with a very simple central nervous system. It has yet to be determined how much of the behavioral variation among individuals is a consequence of such random variation in the development of the central nervous system, variation that is inborn, but not genetic.

The environmental and chance contingency of the mapping between genotype and phenotype arises from the nature of organisms as physical objects. They are intermediate in size between particles and planets and they are internally functionally heterogeneous. As a result, unlike simple physical systems like the movement of planets around the sun, their functions are not the consequence of a few strong causal forces whose parameters govern the outcome. Organisms are the nexus of a very large number of individually weakly determining forces subject to noise at all levels. The consequence for the understanding of the physical properties of organisms, including their individual and social behavior, is that we cannot expect any simple and universal generalizations like Newton's Laws. That is certainly true for the relation between genotype and phenotype.

Gentrification

Loretta Lees, King's College London, Strand, London, UK

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Gentrification has grown from being a small-scale inner city process pioneered by a left-liberal new middle class to being a mass-produced process around the world – 'gentrification generalized.' There are debates over definitions of the process, the kinds of theory we might use to explain and indeed predict the process, and over who is responsible for a process that most academic work is clear, despite its positive rhetoric, has a negative impact on low-income populations.

Origins of the Term

The term *gentrification* first appeared in the writings of the British Marxist sociologist Ruth Glass in 1964, although Glass is said to have used the term earlier than this in an unpublished study of housing in North Kensington in 1959, and an early reference to the word 'gentrification' can be found in the 1888 *Memoirs and Proceedings of the Manchester Literary & Philosophical Society* (p. 39). In coining the term 'gentrification,' Glass was describing a new and somewhat peculiar process that she was witnessing in areas of inner London such as Kensington, Chelsea, and Islington:

> One by one, many of the working class quarters of London have been invaded by the middle classes – upper and lower. Shabby, modest mews and cottages – two rooms up and two down – have been taken over, when their leases have expired, and have become elegant, expensive residences. Larger Victorian houses, downgraded in an earlier or recent period – which were used as lodging houses or were otherwise in multiple occupation – have been upgraded once again. Nowadays, many of these houses are being subdivided into costly flats or 'houselets' (in terms of the new real estate snob jargon). The current social status and value of such dwellings are frequently in inverse relation to their status, and in any case enormously inflated by comparison with previous levels in their neighbourhoods. Once this process of 'gentrification' starts in a district it goes on rapidly until all or most of the original working class occupiers are displaced and the social character of the district is changed. (Glass, 1964: xviii–xix)

Although Ruth Glass coined the term *gentrification* as we know it in 1964, Eric Clark (2005: 260) has argued that "it is careless to turn this into an assumption that we have here the origin of the phenomenon." In fact, Neil Smith (1996: 34–40) had already argued that earlier processes, such as the Haussmannization of Paris, when Baron Haussmann demolished the poor residential areas of central Paris to build new, wealthy tree-lined boulevards to show case the city's famous monuments were examples of gentrification. Gale (1984) also pointed out that gentrification was happening in parts of New York City, New Orleans, Charleston, and the Georgetown area of Washington DC, in the late 1930s. Lees et al. (2008: 5) argued, however, that "the emergence of gentrification proper … began in postwar advanced capitalist cities. It's earliest systematic occurrences were in the 1950s in large metropolitan cities like Boston, Washington DC, London and New York City." The process also had different names in different places: in New York City it was called brownstoning; in Baltimore, homesteading; in Toronto, whitepainting or whitewalling; and in San Francisco, red-brick chic. As Williams (1986: 65) argued: "Many American analysts have been uncomfortable with the term 'gentrification' (with its obvious class connotations), preferring instead labels such as 'back-to-the-city movement', 'neighborhood revitalization', and 'brownstoning', all of which were indicative of underlying divergences in what was believed to be central to this process."

The Stages/Waves of Gentrification

Stage models of gentrification, based on the ecological models of the time, began to develop in the 1970s and 1980s both to explain the process and to predict the future course of gentrification. These models were based on ecological ideas about invasion and succession, ideas that have long been reflected in definitions of gentrification: "The process of gentrification is often similar to that of *invasion and succession*. A few gentrifiers obtain properties in a relatively run-down condition within a small area and improve them, thereby increasing the attractiveness of the area to others who would prefer such a location, so that eventually the entire area (often only a few streets) changes its socio-economic status, and property values are substantially enhanced. Real estate agents and property developers may participate in the process, as they seek to enhance the exchange value of an area and to reap substantial profits from promoting *uneven development* at the intra-urban scale" (The Dictionary of Human Geography, 1994: 216–217, emphases in original).

Clay (1979) was one of the first to produce a schema of the different stages of gentrification. He based his 'predictive' model on observations and data from a number of US cities, including Boston's South End, Philadelphia's Society Hill, San Francisco's Western Addition, and Washington's Capitol Hill. Clay's model moved from Stage 1 (where risk-oblivious 'pioneer' gentrifiers moved into historic neighborhoods, which were 'red-lined,' and renovated property through 'sweat equity' causing little displacement at that time), through Stage 2 (when similar people moved in and small-scale speculation began, more displacement ensued, and neighborhood names were often changed), through Stage 3 (when media and official interest began, developers became interested, displacement continued,

 http://dx.doi.org/10.1016/B978-0-08-097086-8.74013-X

new incomers were much less tolerant of the preexisting community, and banks began to 'green-line' the area), and finally, to Stage 4 (when the process matured and the neighborhood was stabilized, the business and managerial classes moved in rather than the professional classes, rent and sales prices of property were now very high). Writing at the same time, Gale (1979) also designed a stage model of gentrification based on research in Washington DC, he was especially interested in the class and status distinctions between old and new residents in a gentrifying neighbourhood and in displacement of former working-class residents. The differences between Clay's and Gale's stage models of gentrification indicate the different emphases that different researchers place on analyses of gentrification. However, as the process of gentrification developed, it became apparent that models such as these needed to be updated and were losing their predictive value. Hackworth and Smith (2001) produced a more updated model that divided gentrification into three different waves running from 1968 to 1999, divided by two transition phases. The model demonstrated 'the changing state' of gentrification. First-wave gentrification occurred between 1968 and 1972 (this is akin to what Clay and Gale called pioneer gentrification). The global oil crisis of 1973 triggered a transition phase that lasted until 1978 during which gentrification continued and set the stage for a second-wave gentrification from 1978 to 1989, when the process anchored itself in neighborhoods and triggered both displacement and political struggles. Then another transition phase was triggered by recession until 'post-recession' or third-wave gentrification kicked off in 1993/1994. By now, the process had attracted large-scale capital, large-scale developers, and the state. Persuasive as this model was, Lees (2003) showed that mutations of gentrification, such as supergentrification, were already beginning to contradict such models. Supergentrifiers set out to regentrify already gentrified neighbourhoods, such as Brooklyn Heights in New York City, demonstrating no mature or end stage to the process of gentrification.

Definitions, Types, and Shifting Terms of the Debate

Gentrification is a slippery term; definitions and typologies have changed as the process has evolved. Early definitions of gentrification were closely aligned to Glass (1964) description, for example: "By gentrification I mean the process by which working class residential neighborhoods are rehabilitated by middle class homebuyers, landlords and professional developers. I make the theoretical distinction between gentrification and redevelopment. Redevelopment involves not rehabilitation of old structures but the construction of new buildings on previously developed land" (Smith, 1982: 139). But as developers became more involved in gentrification it was apparent that the residential rehabilitation that Ruth Glass had described was only one facet of the gentrification process. As Sassen (1991: 255) explained: "Gentrification was initially understood as the rehabilitation of decaying and low-income housing by middle-class outsiders in central cities. In the late 1970s a broader conceptualization of the process began to emerge, and by the early 1980s new scholarship had developed a far broader meaning of gentrification, linking it with processes of spatial, economic and social restructuring. Gentrification emerged as a visible spatial component of this transformation. It was evident in the redevelopment of waterfronts, the rise of hotel and convention complexes in central cities, large-scale luxury office and residential developments, and fashionable, high priced shopping districts." The types of gentrification that Sassen mentions go well beyond the classic rehabilitation of residential historic properties, to include rehabilitation of nonresidential properties and new-build development. As such, new types of gentrification became parlance–retail gentrification, commercial gentrification or boutiqueification (Bridge and Dowling, 2001; Zukin, 2010), new-build gentrification (Davidson and Lees, 2005, 2010), tourist gentrification (Gotham, 2005), and so on.

Some authors, though, questioned the definition of gentrification earlier than this. The term *rural gentrification* can be traced back to Parsons (1980). It refers to the gentrification of rural areas, describing the link between new middle-class settlement, socioeconomic and cultural transformations of the rural landscape, and the subsequent displacement and marginalization of low-income groups (Phillips, 1993). Phillips (2004) documents the parallel between rural and urban gentrification; both reflect distanciation from the suburbs. The process in the United Kingdom has also been called *greentrification* (Smith and Phillips, 2001) and in the United States *wilderness gentrification* (Darling, 2005): "It is a different story in the wilderness, largely because of the kind of rent that is being capitalized. What gets produced in the process of urban gentrification is residential space. What gets produced in the process of wilderness gentrification is recreational nature" (p. 1022). Phillips (2004) writes persuasively about the need to widen the spatial lens of gentrification studies, and Hines (2010) does this in his discussion of the colonization of rural communities by the ex-urban middle class. Mills (1988) also questioned previous definitions of gentrification in her study of the newly built postmodern landscape of Fairview Slopes, a small neighborhood in inner city Vancouver: "Yet Fairview Slopes does not fit the usual image of a gentrified neighborhood. It is a landscape of redevelopment, and renting is probably still as common as owner occupancy" (p. 186).

Others have produced more focused descriptions of certain gentrifiers associated with certain types of gentrification, for example, the students who are 'proto-gentrifiers' in Darren Smith's (2005) 'studentification' thesis. Studentification refers to the process of social, environmental, and economic changes effected by large number of students (caused by the massive expansion of higher education in the United Kingdom) invading particular areas of the cities and towns in which popular universities are located. Though originating in Britain, studentification has also been adopted in American English (see also Davison, 2009 on Australia) to refer to similar situations in many US college towns. Increasingly though, attention has turned to the role of universities themselves as gentrifiers (see http://www.blackballot.com/harlem-gentrification/columbia-university-and-the-gentrification-of-harlem) – an interesting parallel to the evolution in the process from individual gentrifiers to institutional gentrifiers.

Lees (2003) discusses the supergentrifiers who have led the process of supergentrification or "financification" in certain neighbourhoods that have become the focus of intense

investment and conspicuous consumption by a new generation of super-rich "financifiers" fed by the fortunes from the global finance and corporate service industries. Butler and Lees's (2006) position revolves around Sassen's (1991) argument about the creation of a new class of financial engineers who have successfully commodified the financial services industries, creating new products and great wealth for themselves. The spread of this industry has been such that it has also included those in supporting industry sectors such as marketing, IT, and crucially legal services. It is these very wealthy, 'masters of the universe' who enact supergentrification in neighborhoods, like Barnsbury in London, which have already entered a stage of mature gentrification. Supergentrification is an interesting phenomenon because it poses important questions about the historical continuity of current manifestations of gentrification with previous rounds of neighbourhood change. It also stands against neo-Marxist rent gap–type explanations (see below), which focus on the dialectic of disinvestment and reinvestment, for here the neighbourhood is not disinvested.

Gentrification then is "a highly dynamic process, it is not amenable to overly restrictive definitions; rather than risk constraining our understanding of this developing process by imposing definitional order, we should strive to consider the broad range of processes that contribute to this restructuring, and to understand the links between seemingly separate processes" (Smith, 1986: 3).

Key Theories and Debates

In the early days, gentrification studies were dominated by neoclassical economic theory, and this approach continues today (e.g., several economists have refined bid-rent models to chart gentrification and other shifts in the contours of urban spatial structure–e.g., Brueckner et al., 1999). Social scientists, however, for the most part were not enamored of such an approach. As such, by the 1980s and 1990s, the pages of urban studies journals were dominated by two different theoretical framings of gentrification: a Marxist theoretical camp led by geographer Neil Smith and a humanist (or cultural postmodernist) theoretical camp led by geographer David Ley. The debates were also framed as production versus consumption, economic versus cultural, and structure versus agency (for summaries of these debates and key readings associated with them, see Lees et al., 2008, 2010 and Brown-Saracino, 2010). Neil Smith, like Ruth Glass, was a Marxist, but he was a geographer and not a sociologist, as such he was more interested in space and spatiality with respect to the gentrification process. Smith drew on Marxist notions of uneven development to theorize gentrification; he was interested in the 'locational seesaw' of capital as it was reflected in the successive development, underdevelopment, and redevelopment of spaces in the city. Smith showed how capital in the twentieth century jumped about the city looking for places in which to create profit, first in the suburbs and then in the inner city. Smith (1979) summarized the microdynamics of uneven development in relation to gentrification through his theory of the rent gap. His rent gap theory described the difference between capitalized ground rent – the rent captured under present land use–and potential ground rent – the maximum rent that could be attained if the land were put to a better or higher use. Disinvestment was simply urban creative destruction. In urban areas, new developments (like suburbanization) undermined older investments (in the central city), and land/property owners saw a poor return on sinking more capital into aging property in inner cities. There was a clear spatial imprint – the old inner city and the new suburbs. But as profit margins began to diminish in the suburbs, capital moved back to the city in a search for value. As such, certain neighbourhoods became ripe for gentrification: "The movement of capital into suburban development led to a systematic devalorization of inner and central city capital, and this, in turn, with the development of the rent gap, led to the creation of new investment opportunities in the inner city precisely because an effective barrier to new investment had previously operated there" (Smith, 1982: 149). In inner London as landlords saw the money that could be made from evicting tenants and selling their disinvested properties on to developers – some resorted to winkling (also known as Rachmanism) to get tenants out (see Lees, 1994a).

The rent gap thesis, however, involves concepts that are very hard to measure: nothing like capitalized ground rent appears in any public database; as such the researcher has to construct specialized indicators. For example, Smith et al. (1989) used tax arrears data on the Lower East Side in New York City. Hammel (1999) talks through some of the difficulties with the thesis and how the integration of the rent gap with theories of scale resolves a number of crucial difficulties. However, debate over the rent gap has been complicated by the publication of similar hypotheses – for example, Hamnett and Randolph's (1986) theory of a value gap driving the conversion of London rental flats into owner-occupation (and gentrification), and Sykora's (1993) notion of a functional gap describing the mismatch between urban core land uses under state-socialist conditions in Prague, as market conditions created a land-market gradient in the early 1990s. It became obvious how important local context was to theorizations of uneven development.

David Ley, a humanist geographer, developed new ideas about the "postmodern condition" in his "post-industrial thesis" on gentrification. He was especially taken with American sociologist Daniel Bell's (1973) *The Coming of the Post-Industrial Society*. Ley (1996) argued that a "cultural new class," an expanding middle class of professionals, had instigated gentrification, not capital per se. This new middle class could be identified by their left-liberal politics, lifestyles, consumption habits, aesthetics, and tastes. This new class desired an alternative to the hegemony of postwar suburbanization – urbanism. They were pro-urban, and Ley argued that gentrification represented an "imagineering of an alternative urbanism to suburbanization" (p. 15) and that this could not be captured by explanations of the process that privileged the structural forces of production and housing market dynamics. Ley's pioneer gentrifiers were politically progressive hippies who eventually morphed into more corporate type gentrifiers – or yuppies. The crucial point, as Rose (1984: 56) stated: "[was] that 'gentrifiers' are not the mere bearers of a process determined independently of them. Their constitution, as certain types of workers and as people, is as crucial an element in the production of gentrification as is the production of the dwellings they occupy."

Canadian sociologist Jon Caulfield (1994) interviewed this cultural new class in Toronto and found that gentrification was a form of resistance not just to suburbia but also to the large-scale inner city urban renewal of the 1960s. British sociologist, turned geographer, Tim Butler's (1997) work on London detailed well how this new middle class was different from the traditional middle class and indeed the upper class – in terms of their pro-urban, pro-social diversity, left-liberal politics, and their education and professions. In addition, Butler (1997) showed how gentrification in Hackney was different from gentrification in other areas of London, for example, Islington. Butler with Robson (2003) continued this theme when they looked at six gentrified neighbourhoods in London and found that each of them formed a different 'metropolitan habitus.' They showed how gentrifiers ensured their hegemony over the localities in which they settled and argued that gentrification should be seen as a middle class "coping strategy" (p. 27) in unstable economic times when the middle classes were facing various structural constraints and where the inner city did not provide everything they desired – for example, quality (middle-class) schools.

The proliferation of work on gender and gentrification (on social reproduction, on dual career households, etc.), and on sexuality and gentrification (gay gentrification) was similar to Ley's thesis (see Lees et al., 2008: Chapter 3). As Ann Markusen (1981) summarized: "[G]entrification is in large part a result of the breakdown of the patriarchal household. Households of gay people, singles, and professional couples with central business district jobs increasingly find central locations attractive … Gentrification … corresponds to the two-income (or more) professional household that requires both a relatively central urban location to minimize journey-to-work costs of several wage earners and a location that enhances efficiency in household production (stores are nearer) and in the substitution of market-produced commodities (laundries, restaurants, child care) for household production" (p. 32).

By the mid-1990s, however, researchers had become frustrated with these (arguably) polarized theoretical views (what became known as the gentrification battleground) and began to adopt a more complementary approach (see Clark, 1992; Lees, 1994b). In the late 1990s, attention moved away from theorizing the process toward investigating the influence of gentrification on urban policies and looking at what Martin Phillips (2004) has called gentrification's others. Today, British and North American researchers are focused more on the effects, rather than the causes, of gentrification and on finding alternatives. We can say without any hesitation, however, that gentrification is an economic, cultural, political, social, and institutional phenomenon and that various actors have been and are involved, from individuals to private institutions to the state.

The State Gets Involved

Over time, the state in Europe and North America has become increasingly involved in gentrification. In the early days of gentrification, as is seen in the stage models discussed above, the state acted as a facilitator of gentrification. For example, in London in the 1970s, the state provided home improvement grants (Lees, 1994a; Lees et al., 2008: Chapter 1) to aid gentrification, and in New York City in the 1980s and 1990s the state undertook more revanchist activities, such as zero tolerance initiatives and eviction of the homeless and drug dealers from the Lower East Side (Smith, 1996). By the late 1990s, however, the state was beginning to emerge as a major player in gentrification, and state-led gentrification began to affect neighborhoods in cities across North America and Europe (see Lees et al., 2008: Chapter 5).

In the United States, the Federal Department of Housing and Urban Development (HUD) set about the state-led gentrification of public housing through their HOPE VI program. Drawing on poverty deconcentration arguments, HUD was able to sell gentrification through the concept of mixed communities/social mixing (Lees et al., 2008). They began to replace existing high-rise, high-density social housing projects with new, lower density, mixed-income communities. An infamous example is Cabrini Green in Chicago. In 1994, despite being located next to some of the most expensive real estate in Chicago, Cabrini Green qualified, under HUD guidelines, as the worst case of public housing in the United States and received $50 million to redevelop a portion of the site (Lees et al., 2008). By 'manufacturing' a socially mixed community in areas of poverty concentration, such as Cabrini Green, US policy makers thought that gentrification would

> ameliorate the social isolation of the poor. New more affluent residents will rub shoulders with poorer existing residents on the streets, in shops, and within local institutions, such as public schools. Such newcomers may exhibit possibilities of social mobility and a determination to secure adequate public services that provide existing residents with the kind of role models and contacts the absence of which Wilson [W.J. Wilson, 1987] finds debilitating in the ghetto. (Byrne, 2003: 422)

New evidence collated on mixed communities in Bridge et al. (2011) shows that such a positive scenario is rarely the case. Hyra (2008) has tellingly labeled HOPE VI "the new urban renewal," referring to the displacement of the urban poor as formerly notorious ghettos became dotted with expensive restaurants, health spas, and chic boutiques.

State-led gentrification in the form of mixed communities policy was to emerge not just in the United States, but also in the United Kingdom, France, the Netherlands, Ireland, Canada, Australia, among other countries.

In the Netherlands, a policy of housing redifferentiation began in 1996. Housing redifferentiation was a policy of adding more expensive dwellings to low-income areas by removing inexpensive dwellings through demolition, together with the sale and upgrading of existing dwellings. The idea was to create a more socially mixed population in neighbourhoods via gentrification (see Hulsbergen and Stouten, 2001; Uitermark, 2003). Uitermark et al. (2007) are clear that an influx of middle-class residents into a disadvantaged neighbourhood does not increase social cohesion; rather the contacts between low-income and higher income households tend to be superficial at best and downright hostile at worst.

In the United Kingdom, the New Labor government initiated an Urban Task Force that was especially excited by the Dutch

policy, as it was by HOPE VI. The Urban Task Force Report stated: "In responding to social problems we must avoid repeating the mistakes of the past. Developing large amounts of social housing in one location does not work. Many existing social housing estates have a strong sense of community – often more so than wealthier neighbourhoods – but there is not the economic capacity to make these neighbourhoods work over the long term. As a result, jobs and investment go elsewhere, exacerbating the physical isolation of many of these estates. In future, we must develop on the basis of a mix of tenures and income groups" (DETR, 1999: 45). The Urban White Paper (DETR, 2000) that followed implemented state-led gentrification in the United Kingdom in the guise of urban sustainability. The British government's intention in the late 1990s was to bring the middle classes back to the central city, read gentrification. This was marketed as an attempt to reduce socio-spatial segregation and strengthen the social tissue of deprived neighborhoods; they sold gentrification as something positive (see Cameron, 2003 on positive gentrification or gentrification as a positive public policy tool).

In the 2000s state-led gentrification in Europe and North America (and subsequently further afield) was given a boost by Richard Florida's (2003) creative city thesis: "… since the image of the 'livable city' has become a key aspect of a city's ability to compete in a globalized, knowledge-based economy (Florida, 2003), post-industrial cities have a growing interest in marketing themselves as being built on a foundation of 'inclusive' neighbourhoods capable of harmoniously supporting a blend of incomes, cultures, age groups and lifestyles …." (Rose, 2004: 281). Florida's work on the "creative class" allowed policy makers to promote gentrification while describing their strategies in a new, popular language summarized in the three T's of technology, talent, and tolerance. The creative class that Florida discusses is none other than Ley's (1996) cultural new class described earlier, even if they seem more interested in technology now! State-led gentrification did not just travel in terms of mixed communities/social mix policy but also increasingly so in terms of creative city policy. As Jamie Peck (2005: 740–741) has noted, "In the field of urban policy, which has hardly been cluttered with new and innovative ideas lately, creativity strategies have quickly become the policies of choice, since they license both a discursively distinctive and an ostensibly deliverable development agenda. No less significantly, though, they also work quietly with the grain of extant 'neoliberal' development agendas, framed around interurban competition, gentrification, middle-class consumption and place-marketing." Creative city strategies "presume and work with gentrification, conceived as a positive urban process, while making a virtue of selective and variable outcomes, unique neighborhood by unique neighborhood. And with almost breathtaking circularity, it is now being proposed that these gentrification-friendly strategies should be evaluated, not according to hackneyed metrics like job creation or poverty alleviation, but according to more relevant measures like… increased house prices! … As if this were not circular enough, it is increasingly common for cities to evaluate the effectiveness of their creativity strategies according to their shifting position in Florida's league tables" (Peck, 2005: 764).

Policies of state-led gentrification are intricately tied up with the globalization of gentrification. But as yet it is not proven whether policy transfers and mobilities brought gentrification to cities as far away as Shanghai, Tapei, Cape Town, or Santiago, or whether gentrification in these other places was home grown (Lees, 2012). As Clark (2005) says: "confident proclamations ring out: Gentrification is now global! The problem with this is not if gentrification can be observed in places around the world, but it is again an issue of time: it is now global … The extent of occurrence of the phenomenon from a global historical perspective remains however largely uncharted" (p. 260).

The Globalization of Gentrification

Gentrification traveled beyond the inner city to rural areas and the suburbs; it developed architecturally and aesthetically beyond the historic to the new; it emerged in metropolitan cities, provincial cities, and cities further down the urban hierarchy; but importantly gentrification also went global – it spread beyond North American and western European cities to locations all around the world. Neil Smith (2002) was perhaps the first gentrification researcher to highlight the relationship between globalization, neoliberalism, and the changing role of the state in gentrification. Smith (2002) argued that gentrification is now a global urban strategy linked to a new globalism and a related new urbanism. He made two central arguments: first, that the neoliberal state was now the main agent of gentrification worldwide, and second, that gentrification had gone global and had become what he called gentrification generalized, a strategy connected into the circuits of global capital and cultural circulation. Atkinson and Bridge (2005) followed suit arguing that gentrification was pressurizing cities and neighbourhoods around the globe, and that processes of class colonization were dislocating the urban poor. They claimed: "Gentrification is now global. It is no longer confined to Western cities" (p. 1), and they critiqued this as a 'new form of urban colonialism.' They asked some important questions, for example: "does the fact that gentrification has moved into very different urban contexts – rapidly urbanizing, postcolonial, postcommunist, or commune-capitalist all overlaid by a diversity of cultural and religious forms – inflect, or indeed generate, a very different process?" (p. 1). Unfortunately, their collection of essays did not really answer this question. More recently, Lees (2012) has asked such questions in reference to the new literature on comparative urbanism. She argues that if we take on board ideas from comparative urbanism, we must not assume that gentrification emerged later in non-Western cities, nor that the types of gentrification there are the same as in the West/Global North. Earlier it was stated that the term *gentrification*, with its references to the British gentry and social class system, was not seen as appropriate in the US context. Indeed, as the process has gone global, the process itself has different terms – for example, gentrification began in Finland around 2000 and is called *syrjäytyneiden akanvirta* meaning 'migration of the disadvantaged.' The question Lees (2012) asks is, how important are language and meaning with respect to gentrification? She states that we should avoid the assumption that gentrification is simply 'expanding' toward the global periphery, as if it is an imported new phenomenon that builds upon emerging real estate markets (Peck, 2010). Indeed, it

may be possible to hypothesize that gentrification has taken place in various guises in different parts of the Global South since the 1960s. It may be possible that only the systematic and social scientific observation of these processes is something new, but not the actual phenomena themselves. In this regards, the experiences in the Global South deserve careful attention and revised conceptualization beyond the usually accepted definitions of gentrification outlined here that are confined to the Global North.

Conclusion

Over the past decade, we have seen the rapid and visceral emergence of state-led gentrification in the Global South: processes of gentrification are now changing the centers of cities in China, India, Pakistan, South America, and South Africa (among others). Gentrification began to take off in the Global South (or at least it began to attract the attention of the media and certain academics) at the turn of the twenty-first century, but even then the geographies of a global gentrification presented (e.g., Atkinson, 2003; Atkinson and Bridge, 2005) all but omitted the Global South in any meaningful way. Despite a good discussion in Atkinson and Bridge (2005) about gentrification as a form of neocolonialism – the White Anglo appropriation of the central city – there was no discussion about appropriate theory to analyze either this or how it might play out differently in the predominantly nonwhite cities of the Global South.

What is now required of the gentrification literature is a comparative imagination that can respond to the postcolonial challenge of 'decentering the reference points for international scholarship' (Robinson, 2006: 169), and this will have implications for how gentrification is conceived (questioning the usefulness and applicability of the term *gentrification* in the Global South and indeed elsewhere) and how research is to be conducted (this will push researchers to learn new kinds of urbanism and involve multiple translations throughout the world). Importantly, it entails unlearning the existing dominant literature from the Global North/the West that continues to structure how we think about gentrification, its practices and ideologies.

Abstract

Geoarchaeology uses the techniques, methods, and concepts of the physical sciences to address archaeological questions. Examined here are the major techniques of geoarchaeology that are geared toward: discovering archaeological sites and documenting their internal structure; surveying site formation and disturbance processes; the analysis of soils and sediments; paleoenvironmental reconstruction and the impact of humans on the landscape; the physical analysis of archaeological materials; and the integration of geoarchaeology with social archaeology. Geoarchaeology must be integrated into research programs at the design, excavation, and analytical stages to be most advantageous.

Research that uses the techniques, methods, and concepts of the earth sciences to address archaeological problems is called geoarchaeology. In the important early exposition, *Archaeology as Human Ecology: Method and Theory for a Contextual Approach* (1982), Karl Butzer described geoarchaeology as a collection of techniques for contributing substantive data critical to understanding prehistoric and historic human ecosystems (1982: p. xi). Although geoarchaeology is primarily a methodology, its ultimate objective is to interpret the human past, through an understanding of natural, physical processes that are involved in the formation of archaeological sites.

There are at least eight major concerns of geoarchaeology that must be integrated into research programs at the design, excavation, and analytical stages and include (1) site survey techniques that use geochemical, electromagnetic, and other remote sensing procedures to locate sites or features within a known site; (2) documentation of site-formation processes and the regional context of a site; (3) using a wide array of approaches to characterize activity areas and differentiate cultural from natural (nonhuman) sediments and features, including disturbance processes by biological, soil formation-related pedological, and geological processes; (4) the development and correlation of intra- and extrasite temporal contexts by relative and/or absolute dating; (5) integration of ancient landforms and biological information for the reconstruction of paleolandscapes (Dincauze, 2000); (6) reconstructing paleoenvironments by the identification of pollen, wood charcoal, phytoliths, and seeds; (7) the geochemical analysis of artifacts for procurement, provenance and technology and to document interaction between social groups; and (8) microanalysis of stratigraphy, sediments, and artifacts through micromorphology. Examined here are a few techniques of geoarchaeology that are geared toward: discovering archaeological sites and documenting their internal structure; surveying site formation and disturbance processes; the analysis of soils and sediments; paleoenvironmental reconstruction and the impact of humans on the landscape; the physical analysis of archaeological materials; and the integration of geoarchaeology with social archaeology.

Site Discovery and Definition

Traditionally, locating archaeological sites was accomplished by asking local residents in conjunction with a pedestrian survey; that is, simply walking over the landscape and looking for artifacts and food remains or larger features such as stone house foundations, terraces, or earthworks. In the 1960s with the advent of public archaeology programs – also known as 'contract' archaeology or heritage management studies formulated in response to development projects – archaeological surveys became more systematic, utilizing sophisticated sampling procedures, predictive modeling, and techniques of remote sensing, or archaeological prospecting as it is called in Europe.

Remote Sensing or Archaeological Prospecting

Archaeological prospecting "is considered as an exercise in the deliberate planned measurement and evaluation of physical properties which lead to the detection and mapping of archaeological sites" (Scollar et al., 1990: p. 27). Since all surface indications of many archaeological sites have been obliterated by modern urban encroachment or been buried under soils, excavation has been the technique of choice for locating subsurface cultural deposits. Remote sensing techniques are nondestructive and include aerial photography as well as resistivity, magnetic, electromagnetic, thermal prospecting, and LiDAR (see Conyers, 2012; Hesse, 2010; Lillesand et al., 2004 for a detailed explanation of these techniques).

Aerial Photography and Satellite Imagery

The oldest form of remote sensing, aerial photography, is used in archaeology primarily for discovering field monuments, whether earthen or stone constructions. A huge corpus of aerial photographs exist, some of which were taken during various wars for reconnaissance purposes, others for urban planning, to record changing shorelines, and to document vegetation patterns. However, aerial photos made exclusively for archaeological site discovery are the most useful since they are taken at the appropriate scale, angle, and time of day for enhancing surface features. Prehistoric agricultural field systems in areas such as Mexico and the Pacific Islands consist of low terraces and earthen mounds and embankments which are readily mapped from aerial photographs, saving countless hours of field survey and mapping (Ladefoged et al., 1996).

More recently, technological advances have allowed archaeologists to use satellite images and Google Earth

providing low cost survey methods that are easily accessible (Parcak, 2009). These methods have successfully located previously unknown archaeological sites, can monitor changes through time, such as erosion and the encroachment of development, and can identify and quantify illicit activity (Contreras and Brodie, 2010). Using only an internet connection from any location, vast expanses of land can be quickly and cheaply surveyed without having to physically conduct a ground survey. A further benefit is the ability to survey and monitor potentially dangerous, off-limit or war-torn areas, such as Afghanistan, Iraq, and Syria. However, these methods are not a substitute for fieldwork and can be as easily used by looters or archaeologists.

Other Techniques of Remote Sensing

Once archaeological sites are located, identifying internal structures (intrasite variability) can be accomplished with other techniques of remote sensing including resistivity prospecting, where subsurface anomalies (such as burial pits, compacted ancient floors, or buried house foundations) are mapped by identifying the variation in an electric charge as it passes through the ground (Lillesand et al., 2004). Magnetic prospecting can locate the shape, size, and depth of subsurface anomalies that can then be mapped. Thermal prospecting uses variations in surface temperatures as an indication of subsurface (often cultural) structures (Clark, 2004).

Coring Archaeological Sites

Identifying subsurface archaeological site boundaries, internal features, and differential distributions of artifacts and faunal material can be accomplished by coring (Stein, 1986), especially in conjunction with the analysis of sediment chemistry. Small cores or bucket augers (about 10 cm in diameter) are used to collect sediment samples for the analysis of cultural content and to differentiate cultural from noncultural layers. Since organic matter, carbonates (e.g., marine shells), and phosphates (deposited in the form of urine, excrement, ash, and organic refuse) can increase relative to the intensity of human occupation, these residues are good indicators of past site use and anthropogenic modification, such as agriculture and animal husbandry (Holliday and Gartner, 2007). Distribution of phosphate is used to identify subsurface cultural deposits with a minimum of site disturbance.

Site Formation Processes

The archaeological record is not static, but changes in response to a number of processes – both cultural and environmental (or noncultural). Once deposited in, or on, the surface of an archaeological site, cultural material (artifacts and food remains) and noncultural matter, such as pollen grains and terrestrial sediments, can shift their position or, in some cases, be removed completely. Since archaeological interpretations gain their strength from identifying and analyzing the vertical and horizontal distributions of material within and between sites, it is vital to understand how the positions of these materials may have changed since they were originally deposited – this is the challenge of site formation research defined as the processes, both natural and cultural, that build, disturb, redeposit, and destroy archaeological sites (Schiffer, 1987).

Nonhuman Disturbance Processes

Since the soils and sediments that make up an archaeological site are part of a dynamic open system, archaeological sites are best viewed in a regional context. It is at this level that soil development is best understood because it is influenced by such large-scale processes as precipitation and temperature and erosional agents – including wind and surface water (e.g., rivers, marine shore waves, and sheet wash). Rapp and Hill (1998); (see also Wood and Johnson, 1978) have outlined a number of disturbance processes that affect archaeological deposits. Some of the more important processes include faunalturbation, or the mixing of deposits by animals, especially the burrowing kind (rodents, crabs, insects, earthworms, and birds). Digging burrows not only brings buried material to the surface, but open holes are traps for surface material to accumulate beneath the ground. The mixing of deposits by plants that occurs during root growth and decay is known as floralturbation. Uprooted trees can also bring material to the surface, often from a meter or more below the ground.

Discrete layers within archaeological sites can be homogenized by alternating freezing and thawing episodes which sort sediments by size. This is a problem with sites in the higher latitudes that consist of clay soils that swell and contract in response to precipitation and temperature. Gravity can cause mixing and movement of soil and rock debris downslope, as well as settling or subsidence of relatively large areas. Aeroturbation occurs when wind winnows fine sediments from deposits leaving a 'pavement' of artifacts. This is a significant problem in areas with active sand dune systems. Despite the range of disturbance processes that operate on a regional and site-specific basis, most cultural deposits maintain some order of integrity and, after the site formation processes are understood, valid interpretations are possible.

Human Disturbance Processes

In addition to natural or environmental site formation processes, people intentionally or unintentionally contribute to the formation of archaeological deposits by bringing raw materials to a site such as finegrained rock to fashion into tools; finished artifacts of bone, shell, wood, and stone; cooking fuels, building materials, and food. Many of these items are discarded on site as waste. Even sand grains adhering to feet, after countless thousands of trips to a site, can add significantly to the cultural matrix. Digging pits for earth ovens, trash disposal, burials, small holes excavated for wall or fence posts, or trenches dug for building foundations can displace subsurface cultural deposits. Even stratigraphy that looks intact can contain cultural materials that have been displaced through multiple layers as demonstrated by Khaweerat et al. (2010) for

a coastal midden. Accurate interpretations of the archaeological record can only be made after understanding both noncultural and cultural site formation processes.

Definition of Soils and Sediments

Soils and sediments figure prominently in discussions of site formation processes, so it is essential to know how these terms differ. Soils develop *in situ* at or near the ground surface through the various processes of weathering in conjunction with plant growth and decay, other biological elements, time, climate (temperature and moisture), and local topography. Sediments are particulate matter that has been transported from one location to another by one or more processes such as wind, water, or people.

Principles of Sedimentation

All particles, including artifacts and food remains, found in archaeological deposits can be viewed as sediments (Stein and Farrand, 2001: p. 339) and, consequently, the four principles of sedimentation (Garrison, 2003) apply equally to natural and cultural sediments. First, the source of sediments found at an archaeological site can be unconsolidated particles of bedrock as well as humanly transported stone tools, shells, bones or building stones, to name but a few examples. Second, the transport history of sediments is usually determined by textural and compositional analysis in that biological agents (people, plants, and animals), wind, and water move sediments according to certain physical constraints. For example, wind normally transports evenly sorted sand-sized sediments, while water – in the form of rivers, sea waves, and glaciers – can move anything from clay particles suspended in its volume to huge boulders that are pushed under enormous power. Third, the environment of deposition, in this example, is the archaeological site, but offsite examples can include sedimentary basins, aggrading shorelines, sand dunes, and till and eradict boulders deposited from melting glaciers. And last, postdepositional alterations, discussed above, are caused by people, other animals, plants, and geologic erosional processes.

Sampling Soils and Sediments

Noncultural soils and sediment samples are usually taken from a profile in an erosional exposure or from the sidewall of an excavation unit or trench. Beginning from the bottom up, samples are taken from separate stratigraphic layers or in a continuous column. In the same manner, cultural sediments can be collected from architectural features (walls and floors), middens, streets, burials, and other features such as pits, post-holes, and benches. Collecting micromorphology blocks from these same contexts is also advantageous for understanding mircrostratigraphic events not visible through traditional excavation methods (see Courty et al., 1989). The sample volume varies according to the kinds of analyses undertaken and the size of sediments. For example, small samples of about 20 g are needed to analyze the texture of clays and silts, while several kilograms are necessary for analyzing cultural content or if the sediments are gravel to cobble size. The key is to collect a representative sample of the sediment.

Grains and Particle Size Analysis

Among other things, particle size analysis permits the detection of the agent of deposition (e.g., wind, river, sea) and the environment of deposition such as beach, flood plain, and dune (Waters, 1992). As mentioned above, well-sorted sand is often wind-deposited and certain agents of deposition have particular sediment signatures. Mineral identification of individual grains can suggest a likely source of the sediments, especially if the regional geology is well known. Grain shape (roundness and flatness) can indicate the transport agent, depositional environment, and history. Grains can be, for example, platy or flat; angular, or granular. Roundness refers to the general grain surface curvature and is more a function of mineral composition (certain minerals are harder or softer than others and respond to friction differently), depositional history, and final depositional environment. Grain surface textures, examined under high-power magnification, can be: unworn and angular, suggesting a fresh or minimally transported history; rounded and glossy, the result of transport by running water; or matt-surfaced grains, the result of wind transport. A good review of the analytical methods of sediment analysis can be found in Goldberg and Macphail (2006).

Paleoenvironmental Reconstruction and Human Impact

The relationship of people to the landscape (and here we use 'landscape' to mean the physical and biotic environment) is of worldwide interest, not only to archaeologists, but to biologists and politicians alike, to name just a few. How humans managed their resources through time – whether successfully or with tragic consequences – is of utmost importance to contemporary society, especially as the world becomes increasingly one 'global village.' Archaeology is better positioned than any other discipline to understand the historical details of human–landscape relationships over tens of thousands of years and across an enormously varied set of environmental conditions that posed opportunities and problems for our ancestors.

To document and understand the variation in human–landscape interactions, the analysis of soils and sediments is especially useful when used in conjunction with the differing distribution of floral remains (see Pearsall, 2000, for a review of analytical methods). The analysis of faunal material is also of importance here and is addressed in *Zooarchaeology*. Whether of carbonized wood fragments, pollen, opal phytoliths (minute silica bodies formed in the cells of living plants that can be diagnostic of certain species), or leaves, plant remains are often indicative of vegetation on or near an archaeological site. Wind-dispersed pollen can reveal regional floral patterns. Recovered from dated stratigraphic contexts, vegetation history can be charted over time – before, during, and after human settlement. In essence, archaeological sites hold an historical record of local and regional

paleoenvironmental change, often in response to human modifications to the landscape. The journal *Vegetation History and Archaeobotany* is an excellent source for articles on these topics.

Physical Analysis of Raw Materials and Archaeological Artifacts

A growing area of interest in geoarchaeology is the mineralogical and elemental analysis of raw materials and artifacts such as ceramics, stone tools, amber, glass, metal, and building materials. Analytical results connect artifacts to the geological source and occasionally to the site of production, but also help to identify the human agent in technology and the interrelated web of social practices associated with the procurement and production of objects. The emphasis is on establishing lines of interaction or communication between or within social groups. The diachronic and synchronic distribution of exotic materials is thought to reflect changing aspects of social organization, trade, exchange, early commerce, and extended spheres of influence – topics of great interest to archaeologists.

Instrumental Analytical Techniques

There are many useful techniques for determining the elemental composition of archaeological materials and artifacts (see Garrison, 2003 for a description of various techniques). These include, X-ray fluorescence (XRF), X-ray diffraction (XRD), infrared spectroscopy (IR), neutron activation analysis (NAA), inductively coupled plasma (ICP) and isotope analysis (Collerson and Weisler, 2007), to thin-section petrography which has been used in geologic investigations for over a century.

Ceramics and earthen architecture are manufactured from clay, water, and nonplastic inclusions (temper). Pots were often decorated with an exterior clay slip, incised or stamped with various intricate patterns. Fired bricks occasionally have stamps or makers marks, where sun-dried or rammed earth construction can provide information on production, organization of labor and resource exploitation. Of interest to interaction or provenance studies is the elemental composition of the clay and temper. If the latter consists of crushed rock or terrigenous (land-based) sands, then chemical analysis of the temper may isolate its source. Stone tools, manufactured from, for example, obsidian, basalt, chert, or other finegrained rocks, also can be geochemically analyzed to determine the artifact's geological source. Economically important rock sources were generally well known in prehistory and had a limited distribution, thus facilitating sourcing studies.

X-ray Fluorescence Analysis, Inductively Coupled Plasma-Mass Spectrometry and Inductively Coupled Plasma-Optical Emission Spectroscopy

There are several geochemical techniques that are routinely used to determine the elemental composition of source material and artifacts. Simply stated, XRF analysis consists of bombarding a specimen with primary X-rays. The sample emits fluorescent X-rays that are indicative of the kind and frequency of its elemental composition (oxides, such as iron or silica, are measured in weight percentage, while elements are counted in parts-per-million or ppm). Dedicated computers are used for data analysis, while statistical clustering programs can aid in grouping artifacts with possible sources. Once sources are adequately characterized in terms of their geochemical variability, then unknowns or artifacts can be more confidently assigned to a specific source (see Weisler, 1997 for provenance studies using basalt). Although limited in the range and precision of analyzed oxides and elements, new portable devices are making XRF more accessible to areas where samples cannot be exported or destructively sampled (Shackley, 2011). The most accurate and precise results – and the widest array of elements and isotopes that can be analyzed – must be obtained from more sophisticated geochemical techniques such as inductively coupled plasma mass spectrometry and inductively coupled plasma optical emission spectroscopy. Although the operation of these techniques is beyond the scope of this discussion (see Pollard, 2007), of great interest to archaeologists is the ability to analyze the greatest range of trace elements and isotopes using very small samples (often less than 10 mg) with the highest accuracy and precision thus making artifact source assignments more robust than with other kinds of elemental analyses (Collerson and Weisler, 2007).

Thin-Section Petrography

The study of rocks and minerals in thin section (archaeomineralogy) provides information about how ancient people used materials over time and space as tools, ornaments, pigments, construction materials and other manufactured artifacts, such as ceramics, metals, and glass (Rapp, 2009). Thin-section petrography is used extensively today in sourcing studies when mineral identification is desired. Samples measuring up to 25 mm by 40 mm are cut from ceramic sherds and ground thin enough to pass light through them. Placed under magnification, minerals (such as olivine and feldspar) are identified and texture measured. Within a geologically well-known region, temper composition can be assigned to a particular river drainage (in the example of placer sands), a marine beach, or a larger region such as a group of hills or a mountain range.

Social Geoarchaeology

Geoarchaeology describes and characterizes materials and artifacts but a social geoarchaeology contextualizes and interprets culturally modified materials, contributing to issues of temporality, household archaeology, identity, social memory, and object biographies. Too often, archaeological science is unnecessarily distinct from archaeological theory, even though scholars in both areas share a similar objective: to understand past societies through the medium of material culture. Social archaeology is defined as the "process of knowledge production mediated by material culture and experience" (JSA editorial, 2001), and recent scholarship has demonstrated how all aspects of our physical experience are social, such as landscape,

environment, weather, and climate (Evans, 2003). Social geoarchaeology looks at nature as something nondistinct from culture, where artifacts and deposits are all results of cultural behaviors, actions, gestures, and movements. The geographical distribution and physical and chemical properties of sources and materials allows geoarchaeologists to interpret the material impact on human culture, materiality, and life histories of objects (see Boivin and Owoc, 2004 for case studies). For example, analysis of floor sediments informs on activity areas, storage patterns, and the use of space. Micromorphology of wall plasters and floor deposits suggests the frequency and seasonality of plastering events and the life-history of buildings (Matthews, 2005; Boivin, 2000). Examination of mudbrick compositions revealed individual recipes and household autonomy (Love, 2012). Sediment cores from Crete are used to interpret the process of sedimentation and landscape change from the Neolithic-Bronze Age. Using Pierre Bourdieu's concept of *Habitus*, Jusseret (2010) argues that the sediments and the environment structure and frame the lives of past people, where the environment can impact human actions. Geoarchaeology has long been undertheorized but by providing empirical data on artifacts, sediments, and landscapes, geoarchaeology can significantly contribute to social archaeology.

Geoarchaeology uses the techniques, methods, and concepts of the physical sciences to address archaeological questions. In this short article, we have only touched on a few of the techniques and methods applied to research domains that are of worldwide interest. This subdiscipline of archaeology is continually expanding the range of techniques and their applications to innovative questions. The successful melding of interdisciplinary research, typical of geoarchaeological pursuits, continues to have a bright future.

Geographic Information Systems

Michael F Goodchild, University of California, Santa Barbara, CA, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Geographic information systems (GISs) are defined as software systems. In this article, the relationships between GIS and other activities having to do with geographic information are reviewed. The use of GIS in social and behavioral sciences is discussed as an increasingly essential component of the research infrastructure and as a tool for acquiring and communicating geographic knowledge. Examples are used to discuss the importance of GIS across the social and behavioral sciences. Sources of data are reviewed, and GISs are discussed from the perspectives of client–server architectures, the Internet, Internet-based services, data archives, and digital libraries. GIS use is intimately related to the role of space in scientific explanation. The article ends with a discussion on the future of GIS.

Introduction

A geographic information system (GIS) is best defined as a software system designed to provide services related to geographic data: such services include storage, analysis, transformation, maintenance, editing, visualization, and modeling. That somewhat dry definition masks a record of rapid growth and widespread applications, beginning some 40 years ago. GIS (this article follows the common practice of using the term GIS both in a specific and in a generic sense) is now the focus of a substantial software industry and a user community that probably numbers in the hundreds of thousands or even millions worldwide, and many simpler GIS functions are now familiar to the users of online maps and GPS-based navigation systems. While many of those applications lie in areas of social and behavioral sciences, they also extend across the full range of sciences, industries, and government agencies that deal in one way or another with information about the surface of the Earth, the subsurface, and the atmosphere.

GISs are one of several geographic information technologies that have appeared in recent years. Geographic information is also handled in image processing systems, in the form of aerial photographs or images from space satellites, and many GISs include image processing capabilities. The Global Positioning System (Kennedy, 2010) and its Russian and European equivalents use satellites to allow users to measure their positions on the Earth's surface, with accuracies that range from millimeters to tens of meters depending on the complexity of the measuring device. Earth-observing satellites (Jensen, 1996) capture images of the surface, and are now widely used to map, detect change, discover and invent resources, forecast weather, and measure variables of importance to Earth science. The Internet and the Web are widely used to distribute geographic data from archives and digital libraries and to provide GIS services to remote users.

Today, the potential user of GIS might employ any of a number of hardware and software configurations. A simple Web browser, running on a laptop, an office machine, or a mobile device, can be used to access Web sites that offer a range of GIS services. Such services include generation of standard map products, lookup of the latitude and longitude of a street address (geocoding), and simple analysis and mapping of data. In this configuration, the browser software might be free, though the accessed online services might require a subscription. Increasingly, online services are accessed through apps available for the iPhone, iPad, or Android-based system. GIS might also be employed using a desktop system, such as a PC or Macintosh, running a powerful GIS such as ArcGIS (Environmental Systems Research Institute, *www.esri.com*), MapInfo (MapInfo Corporation, *www.mapinfo.com*), or a free open-source equivalent. Data might be resident on the system's hard drive, might have been created locally, or might have been downloaded from a data supplier.

A social scientist 'doing GIS' might use any one of these configurations, depending on personal skills and needs. The system would provide services that include preparation of simple maps; manipulation of data to overcome issues of map projections; running of statistical tests; and fitting of complex models to data.

Courses in the use of GIS and in methods of spatial analysis and modeling are now offered in almost all universities and colleges and in many high schools. A wide range of educational materials are available in the form of textbooks (see, for example, DeMers, 2008; Clarke, 2011; Longley et al., 2011), Web sites (see, for example, *www.esri.com*), and Web-based courses (see, for example, *www.unigis.net*). GIS software vendors also maintain Web sites with much useful information.

The history of GIS (Foresman, 1998) originated in the 1960s, with the development of the Canada Geographic Information System. Analysis of paper maps is notoriously difficult, because of the awkwardness and unreliability of techniques for measuring simple properties such as length or area, and because of the difficulties associated with overlaying different maps of the same area. Computer technology was applied in the late 1960s and early 1970s to the editing of maps by producing agencies, such as the US Geological Survey, and to the automation of various functions associated with the taking of the Census. But early efforts were crude and expensive, and GIS became widely available to government agencies and corporations only in the early 1980s. Today, the general public is increasingly aware of GIS through Web sites such as *maps.google.com*, which generates several million maps a day for users who need driving directions, and through powerful, easy-to-use packages such as Google Earth (*earth.google.com*).

GIS Essentials

General computer packages to support analysis of data began to appear in the 1960s, led by BMD, SAS, and SPSS. The table is a powerful model for organizing data, by arraying cases in the rows and devoting each column to some property of each case, and early packages took advantage of this commonality by organizing housekeeping and analytic functions around it. Thus means and variances could be computed by column; regression could be readily applied to two columns; and data could be aggregated by computing the mean value of a column for every unique value of some other categorical column. In essence, these packages exploited an economy of scale in software production: once the housekeeping functions for a simple data model like a table had been built, it became very cost-effective to add new functions based on the same data model.

GIS similarly exploits economies of scale, but in this case by supporting not one but several data models. The real geographic world is enormously complex, and there are many different ways of capturing its contents in digital form, all of them involving some form of approximation. Remotely sensed images use a *raster* model, capturing the Earth's reflectance in each of an array of square cells. Because of its simplicity, the raster model has been used as the basis for many GISs, each of them representing data as a series of *layers* of co-registered raster cells (Figure 1), with each layer capturing some distinct variable, such as land elevation, county name, average income, population, or class of land use.

In the *vector* model, the world is viewed as occupied by collections of points, lines, and areas. Points are located by *coordinates*, often latitude and longitude or some universal coordinate system such as the universal transverse mercator (UTM). Lines are represented as *polylines* by connecting an ordered sequence of points with straight lines. Areas are similarly represented as *polygons*, that is, figures with point vertices connected by straight edges. Each point, line, or area object in the vector model is associated with one or more *attributes* which capture the object's significant characteristics. A set of objects of the same type is associated with an *attribute table* by assigning one row of the table to each object and one column to each characteristic.

Figure 1 The concept of layers. Geographic reality is represented by a set (five in this case) of co-registered rasters, each representing the spatial pattern of one variable. Example layers might include soil type, vegetation cover type, ownership, mean annual temperature, or elevation.

Figure 2 shows a simple example of raster and vector data. The same set of census tracts is shown in Figure 2(a) in the form of a raster and in Figure 2(b) in vector form. Today, most GISs include support for both models and for transformations between them. They also support various kinds of map projections, allowing the user to switch readily between latitude and longitude, UTM, and other coordinate systems and to display any part of the Earth's surface in the form of a flat paper map.

One of the most compelling arguments for GIS relies on the ability to integrate information around a common geographic location. A project might involve many different kinds of information, about different themes or variables for a geographic area. Every point, line, area, or raster cell in a GIS database has an associated location, so it is possible to determine the distance between two locations or to place locations correctly on a map. But more significantly, it is also possible to identify all of the information available about a location or to link together two data sets through common location. GISs include functions to determine how much overlap exists between two areas, whether a given point lies inside a given area, or to select all of the points lying within a given distance of a line. To return to a point made earlier, the economics of software production provide great advantages to GIS designers once a basic structure has been laid down, because new functions that work on the same structure can be added very easily.

Certain key GIS functions are particularly relevant to social and behavioral science applications:

1. *Geocoding*, or the ability to convert street addresses to geographic coordinates, and vice versa. This function might be used to associate coordinates with surveyed households, allowing locations to be mapped, integrated with other data, or subjected to various kinds of analysis.
2. The *point-in-polygon* function, or the ability to compare a set of points to a set of polygons, to identify the polygon containing each point, and to combine the characteristics of the containing polygon with those of the point. For example, this function might be used to associate census-tract properties with those of the individuals who live there, or to count the number of points lying in each polygon, or to average their attributes.
3. The *polygon overlay* function, or the ability to combine two sets of polygons, creating a new polygon for every unique area of overlap, and associating it with the attributes of the two polygons that overlap to create the area. By overlaying a map of county boundaries on a map of school districts, it would be possible to estimate the number of children living in each school district based on knowledge of the population density of each county (subject to the assumption that population densities are spatially uniform within each county).
4. The *buffer* function, which identifies the area lying within a specified distance of a given point, line, or area, and gives it the attributes of this object. By combining this with the geocoding and point-in-polygon functions, it would be possible, for example, to determine the addresses of households within a certain distance of a shopping center.

Figure 2 Representation of three adjacent census tracts using raster cells (a) and vector polygons (b). In the raster case, cell size determines the accuracy of boundary positions. In the vector case, each tract is located by specifying the coordinates of its vertices in order.

GIS as Research Infrastructure

GIS software first became widely affordable in the late 1980s, when personal computers powerful enough to manipulate geographic data became available for a few 1000 dollars. Social and behavioral scientists began to invest in its capabilities, particularly in those disciplines that had traditionally adopted a spatial perspective. Archaeologists and anthropologists, for example, began to use GIS software to map and store artifacts at the scale of the dig, to build digital maps of reconstructed landscapes, and to make use of spatial analysis to understand how early societies operated in space (Aldenderfer and Maschner, 1996). Criminologists use GIS to map crime, correlate crime rates with social variables, and examine detailed spatiotemporal patterns of criminal behavior (Wang, 2005). Political scientists use GIS to evaluate districting and to explore the spatial diffusion of political movements (Eagles, 1995). Market researchers and location analysts use GIS to map market potential, model the spatial behavior and choices of consumers, and search for optimal locational strategies (Martin, 1996).

Of all the social and behavioral disciplines, geographers have long claimed a special interest in space, and much of the early work on GIS design and application was strongly associated with the discipline. Geography is often the home department of GIS, though many other arrangements exist, especially at institutions lacking a geography department. The largest number of GIS courses are offered by geography departments, and geography is often the sponsor of campus GIS infrastructure, in the form of labs, software licenses, and data repositories.

In recent years, efforts have been made to develop wider linkages. In the United States, the University Consortium for Geographic Information Science (*www.ucgis.org*) now links over 80 member institutions in an organization dedicated to advancing GIS and its applications through research and education. In Europe, the Association of Geographic Information Laboratories in Europe has a similar mission. National centers have been funded in several countries to pursue GIS research: in the United States, the National Center for Geographic Information and Analysis (*www.ncgia.ucsb.edu*) was founded by the National Science Foundation in 1988, while in Canada, the GEOIDE network was founded by the three national research councils in 1998.

Several journals are devoted to advances in GIS, including the *International Journal of Geographical Information Science*, *Cartography and Geographic Information Science*, *Geoinformatica*, the *Journal of Geographical Systems*, and *Transactions in GIS*. Descriptions of research using GIS can be found in major journals in many application disciplines.

Comparisons have often been drawn between GIS and statistics, as generic tools and concepts used widely across the sciences (e.g., Goodchild, 1987). It is argued that GIS provides the implementation of methods of spatial data analysis in easy-to-use computer tools, just as the statistical packages implement methods of statistical analysis. In this context, spatial data analysis can be defined as a set of analytic methods whose results are not invariant under changes in the locations of the objects of analysis – in other words, location matters. This serves to distinguish these techniques from more familiar numerical and statistical analyses, such as the calculation of a mean, or the preparation of a scatterplot, that do not normally include location or respond to it. Spatial analysis predates GIS, and major texts include those by Berry and Marble (1968), Haining (1990), and Bailey and Gatrell (1995). But the advent of GIS has greatly improved access to these methods. Moreover, it has come at a time when there is increasing interest in visual, intuitive, and exploratory techniques, all characteristics that are readily compatible with GIS. For discussions of the impacts of GIS on spatial analysis, see, for example, Fischer and Getis (2009).

Sources of Data

Maps are highly compressed representations of large amounts of information and extremely tedious to convert to digital form. Two methods are available, both with advantages and disadvantages:

1. *Digitizing*, a process in which a human operator traces information from a map, capturing the locations of features and their attributes using a pointing device and a keyboard. The process is very expensive, since it is difficult to capture complex geographic features rapidly and accurately. With more and more information available in digital form, digitizing is now no longer as important to GIS applications.
2. *Scanning*, in which an automated device captures the information from a map. Extensive editing and error correction are necessary, especially if the map is of low quality, such that scanning is typically as expensive as digitizing.

In the social and behavioral sciences, data are often highly specific to applications and must be rendered into digital form using one of these methods. Thus, an archaeologist may have to digitize the locations of sites or artifacts from manuscript maps or drawings. But, in other cases, the process of database creation will take advantage of the widespread availability of *framework* data or geographic data sets of generic use that already exist in digital form. These include

1. *Topographic maps*, in both raster (in the United States, produced by the US Geological Survey and known as digital raster graphics) and vector (digital line graphs) forms. Various mapping scales are commonly available (in the United States, the most detailed scale is 1:24 000).
2. *Elevation data* in raster form (in the United States, produced by the US Geological Survey and known as digital elevation models). These data sets vary according to the spacing of the grid: for the entire Earth, the best spacing available is several kilometer, but 30 m spacing is available for much of the United States. The Shuttle Radar Topography Mission is a useful source of data at 90 m spacing for all but high latitudes.
3. *Street centerline data* in vector form. These data sets record the locations, names, address ranges, and other information on streets. The TIGER database created and maintained by the US Bureau of the Census covers all of the United States and includes boundaries of statistical reporting zones. These data sets represent streets by single lines and have positional accuracies of tens of meters. Open Street Map is a global project in which volunteers have created a remarkably rich and detailed data set that is freely available.
4. *Imagery from aerial photography*. The digital orthophoto quad is typical of these data sets, with a 1 m ground resolution and a 6 m positional accuracy and available from the US Geological Survey for much of the US.
5. *Imagery from satellites*. These sources include images collected by a number of Earth-orbiting satellites, with spatial resolutions as low as 50 cm.
6. *Municipal databases* created by local government agencies, often in collaboration with utility companies. These are in vector form and often include property boundaries, locations of buildings, and streets represented by double lines. In some countries, notably the United Kingdom, they are produced by government for the entire land area. In the United States, coverage is patchy. Positional accuracies are typically in the meter range.
7. *Gazetteers*, the digital versions of the indexes found in atlases, linking place names to geographic coordinates. These indexes make it possible to translate information recorded by place name to map form for analysis and display. Recently, gazetteer data have been extended to commercial establishments and local points of interest in support of online map applications.

Many of these data sets are created and maintained by longstanding programs of national mapping agencies. Recently, many countries have attempted to place them within broader policy frameworks that emphasize sharing of data, avoidance of duplication, and the setting of standards. In the United States, the National Spatial Data Infrastructure (NRC, 1993) is a leading example.

These data sets provide the framework on which social and behavioral scientists can often hang their own features and attributes. For example, a criminologist might use a municipal database, adding records of crime locations; a sociologist might use reporting zone boundaries from the TIGER database to create maps and analyze data at the census-tract level; and a planner might use imagery to monitor urban growth. Using data that are already in digital form greatly reduces the cost and tedium of database creation.

Unfortunately, the conditions under which such framework data sets are accessible vary widely. In the US, policy requires that geographic data produced by the federal government be distributed to anyone at a cost no greater than that of dissemination. It is often argued that this policy has stimulated growth in the use of GIS and in the geographic information industry generally. But while US courts have held that geographic data are facts and therefore not subject to copyright, in other countries national governments have adopted cost-recovery policies, protected by copyright. Academic scientists in such countries have found various ways of accessing geographic data at lower cost through bulk purchase agreements. Lower levels of government in the US are also not subject to the cost-of-dissemination policy and have made efforts at cost recovery under trademark protection.

While the public sector has traditionally supplied much of the geographic data used by the scientific community, the private sector is today a major supplier, and companies such as Google now manage massive volumes of georeferenced data. Much of this volume originates from users, in the form of user-generated content. The popular Web site Flickr, for example, contains hundreds of millions of geographically referenced photographs, and many tweets are also geographically referenced. Very large geographic databases are being created for internal purposes by insurance, retail, banking, and other corporate sectors. Point-of-sale systems now routinely capture data on grocery purchases, and direct-mail and delivery companies make use of detailed geographic data for scheduling and targeting. These activities have raised privacy concerns, and it is clear that the levels of detail now available to corporations, together with the ability to integrate and merge data based on geographic location, have very significant privacy implications. Much of this activity remains largely outside any regulatory framework, at least in the United States.

Networks

The Internet and Web have had major impacts on GIS. They have made it much easier to share data and to access data remotely. Data can be easily published and disseminated, as can the more sophisticated results of analysis. Indeed, the entire process of scholarly communication and publication is being radically restructured by networking technologies.

It is useful to distinguish two forms of processing of geographic information. The term 'geographic information system' suggests a combination of hardware and software that may or may not be connected to a larger network. It is likely controlled directly by a single user and provides capabilities and functions directly related to the user's needs. On the other hand, the term 'geographic information services' is used to

describe Web sites that offer specific GIS functions in response to user requests. Instead of sending the data to a GISystem, a GIService retains its data, sending only the results of analysis. Esri's ArcGIS Online, for example (*www.arcgis.com*), provides a range of services that include the generation of maps at the request of the user.

GIServices are growing rapidly and are expected to grow much further in the coming years. In addition to avoiding lengthy transmission of data, they allow the custodian of a sophisticated analysis tool to retain control and to upgrade the tool, rather than undertake a complex process of distribution to user sites. Pricing based on services is very different, and perhaps simpler, than pricing based on data (Guenther and Mueller, 1999). GIServices also assume a level of adherence to standards and encourage the development of interoperable tools using common formats and protocols (the Open Geospatial Consortium, *www.opengeospatial.org*, is a major influence toward greater interoperability in GIS).

Several major initiatives are making geographic data more easy to find and access via the Web. In the United States, the federal government sponsors the Geospatial One-Stop (*geo.data.gov*), a catalog and portal to sites offering geospatial data. In Europe, the INSPIRE geoportal (*inspire-geoportal.ec.europa.eu*) provides unified access to the geographic data resources of European Commission's member states. The terms *geolibrary* and *geoportal* have been coined to describe Web sites that allow search for data based on geographic location, including information that is associated with a geographic area but is not a map or an image, such as a planning report.

Space and Scientific Explanation

Ultimately, the value of GIS and related technologies in the social and behavioral sciences will be intimately tied to the role of space in scientific explanation and understanding. Before expanding on that point, however, it is useful to distinguish between normative and explanatory applications. Many applications of GIS may be scientific in their objectivity and rigor, but nevertheless aimed at supporting decisions, developing policy, or solving day-to-day problems. Such *normative* efforts often apply the principles and knowledge of social and behavioral sciences. Moreover, many do so in a spatial context, by combining principles about behavior and society with the specific conditions existing in a geographic area. Thus there are abundant normative applications of GIS, and in recent years the term geodesign has come to encompass this paradigm.

In this section, however, the focus is on those applications that advance scientific knowledge about the world, through observation, experiment, hypothesis testing, and deduction, because such explanatory efforts lie at the heart of the social and behavioral sciences. To what extent can GIS be used as a tool to advance scientific knowledge?

Ideally, scientific knowledge advances through controlled experiment, by varying the conditions under which society operates and observing the response. But although such experiments are common in areas such as agriculture, and GIS is often used as a tool to manage experimental plots, controlled experiments are unlikely to be possible in the case of social and behavioral processes operating at geographic scales. Instead, science must advance through inference, either inductively by inferring the nature of a process from its geographic or temporal expression or deductively by comparing the predictions of theory with reality.

GIS is most strongly associated with *cross-sectional* approaches to observation and inference. A phenomenon is compared across a geographic area, and its spatial variation is compared with the variation in relevant conditions. Inferences are drawn about process, but since the process is not observed directly it is impossible for inference to be definitive. Alternatively, patterns may be used to provide confirmation of hypothesized processes, though again confirmation is never definite. The tradition of using maps as a basis for inference has a very long history, one of the most compelling historic examples being the map made by Dr John Snow of a cholera outbreak in the Soho district of London in the 1850s, which provided evidence of the role of drinking water as the disease vector.

It is often argued that *longitudinal* observation and inference based on change through time is more definitive than cross-sectional inference. But cross-sectional data are widely available from sources such as the Census, and powerful technologies like GIS increasingly make it possible to examine data from both cross-sectional and longitudinal perspectives. Moreover, in recent years, there has been an upsurge in data that are specific in both space and time, raising the possibility of spatiotemporal GIS and real-time analysis. Tweets and other social media, together with large numbers of digitally captured tracks from mobile devices, offer vast new potential for studies of human behavior and social processes.

Geographers draw a distinction between the properties of a *site* and the site's *situation* in spatial context. Many social processes respond both to the conditions at a place and the conditions in the place's surrounding area. For example, choice of residential location is affected by the properties of the available sites and by their surrounding communities and neighborhoods. GIS makes it possible to observe and analyze a site's situation, in the form of maps and images, and also to link one property of a site to other properties through common geographic location. Further discussions of the spatial dimension of explanation, and of the role of GIS, are available in many sources (e.g., Goodchild and Janelle, 2004).

GIS in the Future

There is every indication that the use of computers to handle geographic information will continue to increase dramatically in the future and that the user base will continue to broaden. But trends in the software industry and in society more generally suggest that the nature of GIS will continue to evolve.

In recent years, there has been a discernible trend toward the solution of problems at the local level. It is reflected, for example, in the popularity of *place-based decision making* in the US Environmental Protection Agency, a policy that encourages the solution of problems locally, by local stakeholders. It is also reflected in the efforts to devolve power to lower levels in the administrative hierarchy. In the 1960s, the so-called *quantitative revolution* in geography emphasized the *nomothetic* search for general laws affecting spatial phenomena and saw traditional

geography's approach as *idiographic*, with its stress on cataloging the unique properties of places. Today, there is much interest in quantitative techniques that accommodate spatial variation in parameters and emphasize the role of spatial analysis in exploring local variation. Fotheringham, for example, has identified such variation as one of the most important themes in contemporary spatial analysis and with colleagues has developed the novel technique of *geographically weighted regression* (Fotheringham et al., 2002). GIS provides an ideal platform for such methods, since it makes it easy to analyze spatial data and to display spatial variation.

At the same time, there is increasing interest in several disciplines in the incorporation of spatial effects directly into theory, on the grounds that a system that is spatially distributed, and forced to communicate over distance, is fundamentally different from the perfectly connected systems that have often been assumed in the past. Spatial economics and spatial ecology are now significant areas within the theoretical wings of those disciplines, while geography has a long tradition of explicit theorizing about space. Again, GIS provides an ideal platform for subjecting such spatially explicit theory to empirical test. Finally, the spatially explicit nature of GIS provides an ideal environment for linking normative and explanatory science. The implications of theories for real geographic areas are readily evaluated, and models that incorporate social and behavioral processes can be combined with geographic boundary conditions to provide readily visualized predictions. Thus GIS offers an ideal environment for bridging the gap between theory and practice and a significant clue in the eternal search for relevance.

Abstract

Remote sensing and geographic information systems (GIS) analysis involves the use of technology to gather, manipulate, and analyze spatial data to understand a range of phenomena. Remote sensing entails obtaining information about the Earth's surface by examining data acquired by a device, which is at a distance from the surface, most often satellites orbiting the earth and airplanes. GIS are computer-based systems that are used to capture, store, analyze, and display geographic information. These two approaches are used widely, often together, to assess natural resources and monitor environmental changes. Social scientists can gain insights into fine spatial and temporal dynamics of a range of social phenomena in environmental contexts by analyzing time series of remote sensing data, by linking remote sensing to socioeconomic data using GIS, and developing with these data a range of digital models and analyses. This article examines remote sensing and GIS in general, with an emphasis on the former, and then explores how these approaches may be used together to address a range of issues. It also emphasizes the role of remote sensing and GIS for use by social scientists engaged in the environmental and ecological scholarship.

Analysis with Remote Sensing and Geographic Information Systems

Remote sensing and geographic information systems (GIS) analyses are complementary approaches that social scientists use to gather, manipulate, and analyze spatial data. Remote sensing is the science and art of obtaining information about the earth from a vehicle, which is at a distance from the surface, most often satellites orbiting the earth and airplanes. These craft carry sensors that capture images of the earth surface across a variety of spectra including visible light, heat, and radar. GIS are computer-based systems that are used to capture, store, analyze, and display spatial information (see the entry on GIS for details). These two technologies are used widely across the social and natural sciences to assess natural resources, monitor environmental changes, and understand a range of social phenomena as they pertain to environmental and ecological issues.

In this article, we examine remote sensing, GIS, and their application to social science scholarship in environmental contexts. The modern field of remote sensing began with aerial photography in the twentieth century and matured with the launch of satellite sensors that have acquired multispectral data over the entire globe since the 1970s. A range of natural and human features can be identified within an image via a variety of methods. The analysis and interpretation of remote sensing data typically is performed through image classification and through change detection after the raw data have been preprocessed. GIS facilitates the interpretation of remote sensing data by linking biophysical information measured by remote sensing to maps of natural and cultural landscape attributes, to field measurements, and to socioeconomic information. GIS also offers many different forms of spatial analysis and modeling that draw on these data. Remote sensing and GIS are important approaches for studies aimed at understanding land-use dynamics, its driving forces, and its impact on society. Remote sensing and GIS support the analysis of changing landscapes in a variety of ways: land-cover mapping, monitoring of land-cover change, identification of land-use attributes, spatial stratification and extrapolation of regions based on land-use patterns, development of spatial models, and application to an ever-increasing number of social science questions.

Remote Sensing and the Environment

Humans 'see' the world by sensing electromagnetic radiation in the form of visible light with their eyes and interpreting the resultant signals with their brains. In many respects, remote sensing functions in a similar fashion; a sensor housed in a satellite or aerial vehicle captures images of different wavelength ranges reflected and emitted by the earth's surface. These images are then interpreted by computer, often with human assistance, and processed into spatial data that are then stored, manipulated, mapped, and analyzed. The character of the returned wavelengths depends on surface attributes, such as the composition of the material, surface moisture, and state of vegetation. Different features can be identified within an image based on the specific 'spectral signature' (or specific combinations of wavelengths) of different surfaces, such as the green of a forest or gray of concrete, and their spatial patterning, such as the readily identifiable edges of agricultural fields or the branching of road networks. For environmental and ecological research, a good understanding of the biophysical processes controlling the radiation of a surface is necessary to interpret the remotely sensed signal in terms of surface attributes. Forest cover, for example, can exhibit varying spectral signatures depending on age of the trees, their dryness, or degree of thinning.

Spectral, Spatial, and Temporal Domains

Remote sensing platforms vary in their spectral, spatial, and temporal characteristics or domains. Spectral range refers to the part of the electromagnetic spectrum in which the sensor operates. The term 'multispectral' denotes a sensor that can capture many different slices or 'bands' of the spectrum (e.g., several shades or red, green, and blue in the visible wavelengths) while panchromatic refers to a sensor that collects one electromagnetic band (e.g., resulting in black and white or greyscale images). Some sensors are termed hyperspectral because they can capture hundreds of discrete parts of the spectrum (Jensen, 2005; Campbell, 2007). Consider the range of different approaches and sensor characteristics:

- In the visible and near-infrared (heat) range of the electromagnetic spectrum, the land surface generally is characterized using vegetation indices, which are arithmetic combinations of spectral bands. The most widely used of these indices is the normalized difference vegetation index. Vegetation indices derived from remote sensing data are related to several variables quantifying vegetation activity and state, such as the fraction of photosynthetically active radiation absorbed by the vegetation canopy, canopy attributes (e.g., green biomass or green leaf area index), or state of the vegetation (i.e., vegetation vigor or stress). Seasonal variations of vegetation indices are related to vegetation phenology and biome seasonality.
- In the thermal range of the spectrum, the heat of the land surface can be derived and is related to surface energy balance, moisture availability, and evapotranspiration. Empirical studies have demonstrated the usefulness of thermal data to locate dense forest boundaries and monitor the growth cycle of crops, including for irrigated systems.
- Active sensors are those that emit radiation and measure how much is returned. Light Detection and Ranging (LIDAR) involves pulses of laser light that can create high-resolution representations of 3D surfaces. Microwaves are also used, where the intensity of microwaves returning from a given surface depends on the geometric characteristics of the surface (i.e., shape and orientation of objects, as well as their surface roughness) and its electrical characteristics (i.e., reflectivity and conductivity of materials). Both active and passive microwave sensing are possible, where active systems (commonly known as radar) supply their own source of energy or illumination while passive systems sense energy that is naturally emitted or reflected from the Earth's surface, albeit at extremely low levels. The capacity of microwave remote sensing to collect data in all weather conditions combined with the fine spatial resolution of the data opens promising avenues for land-cover assessment and monitoring. This technology has, however, not yet reached the same operational level as optical remote sensing.

The spatial domain refers to the resolution of the sensor (the smallest discrete area it can identify on the ground), its range or extent (the amount of area it can capture at one time), and the spatial patterns that may be discerned from an image. A major attribute of a landscape is its spatial pattern, namely the arrangement in space of its different elements. The concept of landscape spatial pattern encompasses, for example, the patch size distribution of forests, the location of agricultural plots, the shapes of fields, or the number and configuration of landscape elements. Landscape spatial pattern is seldom static due to natural changes in vegetation and to human intervention. Remote sensing offers the possibility to analyze changes in spatial pattern at the scale of landscapes. Textural information of images can be measured using a variety of indices such as variance or mathematical morphology.

The temporal domain of a sensor can refer to the amount of time any given snapshot covers and how frequently a given area is sampled by the sensor. Snapshots are usually instantaneous (akin to the way that a camera takes a photo at a single instant of time) but some sensors will average electromagnetic radiation collected over a short period of time. Aerial imagery is collected at an interval chosen by the producers but is usually flown on annual or less-frequent basis given the expense (although the advent of drones, or unmanned aerial vehicles, may make aerial remote sensing much more available). Satellites, in comparison, are expensive to place in orbit, but once aloft they capture imagery on a very frequent basis, ranging from a couple of weeks down to a few days. This frequency, also termed the return interval, can affect the utility of imagery for any given use. For instance, fast-moving phenomena like flooding may require frequent aerial imagery, while seasonal monitoring of deforestation trends can be accomplished by platforms with a lower frequency.

Remote Sensing Platforms

There is an ever-increasing number and variety of sensing platforms suitable for environmental and ecological investigations. Technological considerations combined with cost and desired use have resulted in several families of sensors with comparable characteristics.

- Moderate spatial-resolution platforms are characterized by a number of satellite sensors that have been acquiring multispectral data over the entire globe since the 1970s, at a spatial resolution of dozens of meters. The most widely used among these sensors are Landsat Multispectral Scanner (spatial resolution of 80×80 m), Landsat Thematic Mapper (30×30 m), and SPOT High Resolution Visible Imaging Instrument (20×20 m for the multispectral product and 10×10 m for the panchromatic product).
- Coarse resolution sensors include the Advanced Very High Resolution Radiometer (AVHRR) on the NOAA series of orbiting platforms, which have been used widely for monitoring changes in the attributes of the Earth's surface. These data cover the period from June 1981 to date. The daily NOAA AVHRR Local Area Coverage data have a spatial resolution of about 1.1 km, which is well suited for monitoring seasonal vegetation dynamics at the scale of the landscape. Other useful sensors with a 1-km resolution are the ERS Along Track Scanning Radiometer, SPOT VEGETATION, and the Moderate Resolution Imaging Spectroradiometer, which also has some sensors with a finer-scaled 250-m resolution that is used for a range of applications.
- Fine spatial resolution sensors are capable of generating imagery with spatial resolutions as fine as 1 m or lower in

panchromatic mode and 4 m in multispectral mode. These systems are also characterized by short temporal resolution, with repeat intervals on the order of days. Such imagery also provides greater spatial details on the land surface and opens new applications especially relevant for social sciences, such as urban studies. Much of the data from fine resolution sensors comes from commercially operated satellites such as GeoEye and WorldView-2.

- Several active microwave sensors are also available: the Synthetic Aperture Radar (SAR) on the ERS-1 and JERS-1 satellites, and the Advanced SAR sensor as part of the ENVISAT mission. The cloud-penetrating capability of microwaves makes them an ideal tool for work in areas with a permanent cloud cover. LIDAR is increasingly common through national and state initiatives. While coverage is patchy, a growing number of governments are conducting surveys of entire jurisdictions, and the library of private data is expanding very quickly.

Developing Remotely Sensed Data

Just as humans must mentally interpret signals garnered with their eyes, remotely sensed images must be developed from the raw electronic signals collected by sensors into data suitable for human interpretation and computer processing. This process is comprised of two stages: preprocessing and analysis. The analysis stage in turn consists of image classification to generate land-cover maps and, if desirable, change detection to monitor land-cover changes (Jenson, 2005; Warner et al., 2009).

Preprocessing turns the raw images from the sensor into a format suitable for analysis. This stage corrects geometric distortions and georectifies the data, which entails positioning the image with respect to geographic coordinates. It may also modify and enhance the images, including transforming multispectral data into simpler formats amenable for subsequent analysis. Overall, the purpose of these operations is to transform the image data into a form for which earth surface attributes can be readily interpreted by computers and humans.

Images are then classified, in that labels are attached to spatial sampling units (the pixels) in view of their response in different spectral ranges. Vegetation and water, for example, have characteristic responses in the visible and near-infrared ranges that make their associated pixels straightforward to identify. It may also include their spatial attributes, such as texture or pattern, or temporal changes, such as predictable seasonal changes in vegetation cover. The most commonly used classification techniques are based on statistical methods, although more advanced techniques are continuously being developed. For example, contextual classifiers label a pixel in the context of its neighbors in space and thereby exploit spatial information of an image, such as more readily discerning the boundaries of objects on the surface. Another approach is the use of neural networks, computer programs that mimic the operation of the human brain to bring together a collection of simple classifier algorithms to solve a complex classification problem.

Another analytical step, usually pursuant to classification, is creation of time series of remote sensing data that can be used to monitor changes in landscapes. Classic land-cover change detection techniques are based on the comparison of sequential land-cover classifications. For every sampling unit of these classified images, the land-cover categories at the two dates are compared. The comparison of successive maps can result in failure to detect subtle changes when land-cover classes are too broad. Thus, rather than detecting changes on the basis of land-cover categories, change detection is often better performed on the basis of the continuous variables defining these categories, whether these are reflectance values measured by a satellite sensor or biophysical attributes derived from these sensors (e.g., percent forest cover). Change detection is an area of ongoing research and development (Coppin et al., 2004; Kennedy et al., 2009).

Geographic Information Systems

A GIS offers a powerful approach for handling spatial data. It is designed for the collection, storage, and analysis of objects and phenomena where geographic location is an important characteristic (Longley et al., 2010). GIS data are of two primary kinds: locational and attribute. Locational data specify the spatial position of entities or phenomena, while attribute data describe their characteristics. The location of a building, for example, can be specified in a spatial coordinate system such as longitude and latitude, while attributes describe characteristics such as stories or roofing style. Both components – location and attributes – are usually joined into a single data model, or an internally consistent system of storing data on the computer. The two most common models are termed raster and vector. The raster model has its origin in remote sensing images and their square pixels or cells, where a layer of these cells represents a discrete variable such as elevation or land-cover classes. The vector model instead encodes the world as points, lines, and areas and stores a series of variables associated with these geometric entities.

Once data are stored in an appropriate data model, the GIS offers a range of operations to operate on these data. Data management capabilities include functions needed to store and retrieve data from an underlying database or across the internet and transform the data model, projection, or coordinate system. GIS automates many analysis and data manipulation functions, including variable classification and reclassification, overlay operations, neighborhood operations, spatial interpolation, statistical analysis, and analysis of connectivity. The output or reporting functions of a GIS can be used to produce maps, tables, or statistical results (see the entry on GIS for details). GIS also offer a range of modeling and analytical methods for sophisticated analyses such as representing hydrological flows, transportation modeling, or view-shed derivation.

GIS facilitates the interpretation of remote sensing data by virtue of matching data from images with other forms of spatial data via their location (Merchant and Narumalani, 2009). Examples include linking biophysical information measured by remote sensing to maps of natural and cultural landscape attributes (e.g., soil type, topography, accessibility as measured by various distances), field measurements (e.g., crop yield or water quality), and socioeconomic information derived through household surveys and other sources (e.g., indicators of well-being, rate of population growth, agricultural input

use). Scholars across the social and behavioral sciences use GIS to understand myriad issues and by focusing on quantitative spatial analysis and using basic spatial concepts, such as the neighborhood or population density, in their research (UNESCO, 2010).

Application of Remote Sensing and GIS to Social Sciences of Environment

Social and behavioral scientists use remote sensing and GIS to study social phenomena within the environmental and ecological realms. These studies often rely on 'socializing the pixel,' or discerning information embedded within spatial imagery that is directly relevant to the core themes of the social sciences, and using it to inform the concepts and theories pertinent to those themes (Geoghegan et al., 1998). Creating a direct link between spatially explicit land-cover information, as derived by remote sensing, and information on land-use change processes requires the ongoing development of new methods and models, which merge landscape data with data on human behavior. The majority of this work uses land use and land cover as the linchpin for analysis.

Land Use and Land Cover

One of the preconditions for using GIS and remote sensing to understand social processes within an environmental context is an understanding of land-use dynamics, including the driving forces and societal impacts (Liverman et al., 1998; Verburg et al., 2011). Remote sensing is used widely to map land cover and land use. Classification algorithms generally succeed in identifying from about a dozen land-cover classes, including several succession stages of vegetation. Achieving this level of detail requires, however, a set of georeferenced field observations from a sample of locations. Many current sensors do not identify settlement types or different cropping systems very well, objectives that are increasingly desirable and possible with fine-scaled platforms. Remote sensing also facilitates monitoring changes in the spatial patterns of landscapes caused by land use. Change detection can be used to identify dynamics such as an expansion of the area under permanent or shifting agriculture, urban growth, or increase in eroded areas. Quantitative estimates of rates of deforestation are derived from time series of remote sensing data, for example, and remote sensing has been used in semiarid regions to assess dryland degradation and to identify transformations of land use and cultivation. Remote sensing can also identify land-cover change 'hot spots,' defined as areas where high rates of land-cover change have been observed based on indicators such as land-cover fragmentation, occurrence of fires, and opening of new roads. Finally, remote sensing in combination with GIS allows identification and measurement of key socioeconomic and ecological characteristics of land-use systems, such as different forms of cultivation and land-use trends (Buenemann et al., 2011).

Spatial Stratification and Spatial Extrapolation

Remote sensing and GIS allow for the extrapolation of local observations to larger areas. A common problem of in-depth investigations of land-use dynamics is that they require a large data-collection effort in the field, at the household and plot levels. Remote sensing, by measuring indicators of land use, helps to define regions characterized by a similar land use and to identify spatial stratification of a study area in terms of land-use patterns. As a result, findings obtained over specific sites within a sampling unit that is homogenous in terms of land use can be extrapolated more readily to other areas with the same characteristics. Spatial stratification that is performed before field surveys can be used to fine-tune the sampling design and identify villages or households that will be used for in-depth data collection and investigation. This strategy leads to an optimized data-collection effort. Relatedly, the spatial pattern of a changing landscape can provide insight into the processes of land-cover change. Certain types of land-use change tend to fragment the landscape (e.g., expansion of smallholder farming, small-scale logging, overgrazing around deep wells), while other land-use changes increase landscape homogeneity (e.g., mechanized cultivation or ranching over large areas). For example, in a classic study of land-use intensification (Guyer and Lambin, 1993), remote sensing analysis provided a means of matching the patterns from a haphazard sample of households with that of a larger population, based on a few variables that were estimated both by household survey (on the sample) and by remote sensing (on the entire population). The results tended to give greater confidence to inferences from the sample about ecological dynamics.

Linking Household-Level Data with Remote Sensing Data

There is an ever-expanding array of methods for merging socioeconomic household survey data with remote sensing-based information (Liverman et al., 1998). The major challenges of this work are twofold. First, defining appropriate spatial observation units, especially the appropriate level of aggregation of information derived from the domains of social phenomena and natural environment. Second, developing appropriate linkages between household-level and remote sensing data sets. While conceptually straightforward, these links can be difficult to implement operationally. In remote sensing, the unit of observation is the pixel, a division of space that is usually not directly associated to any social science unit of observation, such as individuals, households, or villages. Establishing the correspondence between biophysical and socioeconomic variables requires taking into account the unit of decision-making, units of landscape transformation, and the spatial scale of ecological processes, such as a watershed or landscape form. Linking remote sensing observations to socioeconomic data at the scale of the administrative units, which were used for the collection of socioeconomic data leads to a loss of information as it obscures the variability within the units. Researchers have attempted to integrate remote sensing observations and field surveys at finer levels of aggregation, such as at the scale of individuals, households, or villages (Fox, 2003).

Spatial Modeling

Modeling-based scholarship joins remote sensing and GIS. With the application of remote sensing technology to the

monitoring of land-use changes, for example, it becomes possible to integrate more explicitly spatial relationships into models of land-use change. It is also possible to apply and test these models at a finer spatial resolution and with samples comprising smaller geographic units, such as individual landscape units. Spatial models are born from the combination of remote sensing, GIS, and modeling approaches ranging from multivariate mathematical models to hybrids of agent-based modeling and other simulation methods (Parker et al., 2003). Their emphasis is on the spatial distribution of landscape elements and on changes in landscape patterns, since spatial patterns detectable at a variety of spatial scales via remote sensing provide the most obvious link between spatially explicit land-use change models and remote sensing analysis. Remote sensing also offers a powerful means to calibrate and validate these models by comparing actual and predicted land-use and land-cover patterns, and by comparing the level of fragmentation of the landscape. The goal of these models is the projection of future landscape patterns, often under varying regimes. This joint remote sensing and spatial modeling approach has been applied to a range of land change domains and their associated ecological and socioeconomic dimensions, including tropical deforestation or dryland degradation, desertification, and coastal erosion (Lambin, 1997; Parker et al., 2003).

Environment and Society

While land-use and land-cover research serves as the linchpin for many social science applications of remote sensing and GIS, there are other research domains that use these approaches to address social issues within the realm of environment and ecology. A fast growing area of research concerns the application of remote sensing and GIS techniques to analyze the relationship between public health and the environment, as researchers use these techniques to map disease clusters, model exposure to environmental hazards, and evaluate access to health services (Cromley and McLafferty, 2012). Research is not limited to present-day issues, as archaeologists, for example, have used GIS software to map the locations of artifacts at the scale of the dig, to build digital maps of reconstructed landscapes, and to make use of spatial analysis to understand how early societies operated in space (Wheatley and Gillings, 2003). Remote sensing and GIS are increasingly coupled to examine hazards, including short-term events such as coastal flooding and fires, to longer terms threats posed by sea-level rise (Allen and Wang, 2010). The combination of GIS and remote sensing is also increasingly used to understand features of the urban environment, such as water quality and imperviousness or the changing composition of greenspace (Liang and Weng, 2011; Patino and Duque, 2013). These examples are just a few of the growing number of the application of remote sensing and GIS to social and behavioral science topics within an environmental context.

Abstract

Out of the set of practices, know-hows, and knowledge, which allowed human beings to transform the Earth into their habitat, geography grew up under the guise of vernacular, corporate, and then scientific narratives. It then developed as a science of terrestrial locations and cartography, a description of regional diversity, a natural science of environments, an analysis of the impact of distance on human life, an interpretation of people's experience of nature, place, and society. This history is more that of a coexistence of perspectives than that of displacement of paradigms.

Research on the history of geography developed early, but it remained for long centered on the discovery of the Earth by Western explorers. The emphasis on the evolution of geographic thought developed mainly in the twentieth century. It took momentum in the 1960s and 1970s, as exemplified, for instance, by the series *Geographers: Biobibliographical Studies*, published by Mansell since 1977 and then as an e-book by Continuum. Even with this new interest in the history of ideas and their social context and significance, this research remained focused on Western tradition. Contributions relative to precontact geographies and their influence on modern forms of geographic thought in non-Western countries remained exceptional.

The history of scientific geographic thought was influenced from its beginning, in the fifth century BC, by vernacular practices, corporate skills, and the dynamics of narratives. It was built along five programs: (1) the geometric representation of the Earth's surface and its cartographic expressions, (2) the literary description of the Earth's surface, (3) the search for a naturalist form of explanation, (4) the adoption of a social science type of explanation, and (5) the understanding of the experience of the Earth developed by human beings. These traditions are not exclusive paradigms, but complementary approaches which coexisted for long periods.

General Conditions

Vernacular, Corporate, and Scientific Geographies

As a scientific discipline, geography has a long history. Its practice goes back to the time of Herodotus (484–425 BC) in the fifth century BC. The term itself was used in *De Mundo* attributed to Aristotle in the fourth century BC. Geography deals with orientation, the location of places, the surface of the Earth, the features which characterize it and the way people conceive and experience places, the Earth, and the Cosmos. It means that geography existed as a practice of daily life before the development of scientific thought. People had to find places, evaluate the value of soils and the best way to farm them, detect and exploit mineral ores, etc. Through the names they gave to places, they developed the first – and purely oral forms – of geographic information systems. Many of these vernacular practices and knowledge coexisted simultaneously with the formal development of the discipline.

Since geography gave information regarding distant places, the ways to reach them, their economy, population, and culture, it was important for rulers. Governments relied either on empirical knowledge accumulated by local persons or on objective evidence gathered by their cartographic, statistical, and ethnographic services for the management of a territory. In the first case, the local agents of the sovereign knew the country they were in charge of so well that they could develop policies of their own. Hence, there was a tendency for all governments to develop centralized forms of control, for which they needed special forms of geographic knowledge – and more sophisticated forms of geographic information systems. Modern enterprises also had to develop geographic skills. They had to locate resources, exploit them, and distribute goods. A part of modern geography was linked with their activity.

The history of scientific geographic thought had always been situated in this context, with an eye to the type of practices used by ordinary people as well as to the skills developed by administrative services in gathering and interpreting spatial data. The discipline was institutionalized for several reasons:

1. the will to provide the state (or other power institutions) with valuable knowledge for domestic control or overseas expansion;
2. a curiosity for the low culture forms of geographic lore and their preservation; and
3. the will to provide the citizens of modern nation-states with an image of their country and the rest of the world in order to build or strengthen their national identity and explain how the contemporary world is working.

Geographic Narratives and the History of Geographic Thought

Geographic thought was expressed through standardized forms of narratives. The history of the discipline is partly that of the transformation of geographic discursive fields. What were the publics aimed at, the rhetoric used to attract or convince them, and the type of knowledge judged convenient for them? In Greek and Roman times, for instance, according to one of the established geographic genres, geography was often presented as the account of a journey made by Icarus.

From the Renaissance onward, geography often developed as narratives on the newly discovered lands and the strangeness of their inhabitants. It sometimes took the form of universal

geographies, i.e., pictures of all the places and countries of the Earth. In other cases, it was made of quantitative assessments of the population, activities, wealth, and military assets of the provinces of kingdoms in order to facilitate their control. During the nineteenth and twentieth centuries, geographers developed other types of narratives: the description of exotic places for tourists and the analysis of national territories for the civic instruction of young people.

Geography is a complex discipline. Its changes are partly explained by the ways it was institutionalized and partly by the evolution of the discursive fields that geographers developed in order to gain a large readership. However, its transformation mainly reflects the dynamics of its scientific purposes. It is convenient to distinguish five different scientific programs that were transformed into traditions later.

The Five Approaches in Geography

Geography as a Science of Terrestrial Locations: Cartography

The first program was linked with the problems of orientation. In order to build a reliable system of place locations, Greek geographers discovered that the best solution was to rely on an abstract grid of reference (Jacob, 1991). The idea appeared with the first forms of mapmaking. For the Ionian mapmakers in the late sixth and early fifth centuries BC, all territories had geometric shapes. The idea of spherical coordinates, which appeared in the third century BC, was conducive to the first scientific cartography. At the same time, it provided a coherent grid of reference for locating places – a scientific basis for geographic information systems. As expressed by Ptolemy (AD 98–168), geography became "the sublime science which reads in the sky the image of the Earth."

The Earth is a sphere and terrestrial positions, i.e., longitudes and latitudes, can be measured through the observation of the Sun and stars. Erastothenes (273–192 BC) was the first to develop this line of research. Hipparchus (second century BC) proposed the idea of geographic coordinates. In the second century AD, Ptolemy synthesized the accumulated data in this field. His contribution was preserved and improved by Arabic geographers during the Middle Ages. The rediscovery of his texts in the fifteenth century marked a new start in the history of geographic thought. In the seventeenth century, Bernhardus Varenius (1622–50) modernized the cosmographic approach through the introduction of the Copernican view of a Sun-centered universe.

The major problem for this conception of geography came from the impossibility of keeping time, so that astronomical observations were unable to give a measure of longitude – a weakness which persisted from antiquity to the discovery of the marine chronometer by John Harrison (1693–1776) in 1735. Until the mid-eighteenth century, one of the main tasks of geographers was to compile data relative to distances in travel accounts. From the mid-eighteenth century, mapmaking became the task of specialized engineers and scientists. They provided geographers with the topographical maps they needed.

Geographers ceased to be responsible for the basic cartography, but the problems of location, mapmaking, and the building of geographic information systems remained important for them. Their role changed; they learnt in the nineteenth century to use statistical sources to produce thematic maps. During the twentieth century, remote sensing facilitated the gathering of data on land use, vegetation, temperatures, atmosphere, etc. Thanks to computing facilities, the building of geographical information systems has recently become easier; one of the most prized skills of contemporary geographers is to provide administrations or firms with this new cartographic aid to decision-making.

Thanks to cartography, geographers were the first who were able to describe the Earth as seen from the sky – the Icarus' viewpoint, according to Greek geographers. It was essential for getting an objective description of the face of the Earth and its regional divisions.

Geography as Description: The Regional Approach

The second agenda developed by geographers was the description of the Earth's surface and its regional differentiation. During antiquity, it was illustrated by Herodotus, Strabo (64 BC–AD 20) and Marinus of Tyre (first or second century AD). Arab geographers improved much of the knowledge of the Middle East, India, the Far East, and Africa south of the Sahara. With the great discoveries, the program became really worldwide.

The main problem was what to describe and how to describe it? Thanks to the map and the vertical perspective it offered, geographic description was different from the travelers'; it was not structured along itineraries, but on the apprehension of regional units as seen from above. Such a perspective allowed for the contraction of much information, but it destroyed the link between direct observation and description, hence the dryness of many descriptions until the eighteenth century.

Because there was no standardized vocabulary to speak about the details of topography, rocks, plants, animals, and human activities, geographers were unable to grasp the real world in their narratives. Sometimes, they preferred to provide their readers with information on local mythology (in the Greek and Roman times), the history of Christianity (during the Middle Ages), and the local coats of arms and heraldry (in feudal Europe). In a way, the travel accounts of the Middle Ages and the Renaissance are generally more interesting for today's geographers than the geographical publications of the time.

Everything changed in the eighteenth century, with the development of natural history and a new curiosity for human activity. The work of Linné in botany and zoology, a few geologists for rocks, and the first agronomists for rural life, created the technical terms geographers needed in order to write precise descriptions of the world. Thanks to Jean-Jacques Rousseau (1712–78) and Johann-Heinrich Pestalozzi (1746–1827), geographers began to offer descriptions on two scales: one was based on both fieldwork and direct observation, and the other on the synthetic vision of the map-reader. Carl Ritter (1779–1859), one of the pioneers of modern geography, has been trained in a Pestalozzian school, just as Elisée Reclus (1830–1905). Alexander von Humboldt (1779–1859) discovered the value of first-hand contact with landscapes through his training as a natural scientist and his contacts with

Georg Forster (1754–94), who was on Cook's second voyage around the world.

The quality of geographic description kept increasing with the development of new scientific fields: pedology, meteorology, and climatology on the natural side of the discipline, and agronomy, demography, and social and cultural anthropology on the human one. Many of these research fields were initially explored by geographers and then turned independent.

Because of the improvement of geographical descriptions, geographers perceived their discipline in a different way: they began to consider that one of its major advantages was to deal with the real world. The idea that geography was a science of concreteness appeared. Geographers did not consider themselves only as scientists; description was an art, so that they had to display a literary bent.

During all of the nineteenth century and a good part of the twentieth, when writing descriptions, geographers felt the need to provide impartial views of the world since their work was based on objective observations. They considered that the descriptions and modes of regionalization developed by laymen were subjective and as such, not reliable. They preferred to ignore them.

Geography as Explanation: The Perspective of Natural Philosophies and Natural Sciences

As soon as description progressed in the eighteenth century, a third task appeared for geographers: they had to explain the distributions they observed. A precise description was necessarily conducive to questions about the causes responsible for the patterns read on the maps or the features discovered through fieldwork. Geographers had to give an explanatory dimension to their analyses.

During the first half of the nineteenth century, the main interrogation was about the interaction of natural features, their mutual conditioning, and their influence on the destiny of human groups. In the seventeenth century, Varenius had opened the way through his analysis of position. In order to explain terrestrial distributions, he stressed the role of latitude and of the major topographic accidents. He opposed inland and coastal locations. In the first half of the nineteenth century, this approach was transformed into a coherent paradigm: the analysis of position, well exemplified by Alexander von Humboldt and systematized by Carl Ritter. The major factors in the shaping of the Earth and the explanation of regional distributions were latitude, altitude, continental versus coastal locations, and the patterns of mountain ranges and coastlines. This kind of analysis had to be developed at different scales.

Geographers used these tools to explain the distribution of particular natural features: the altitudinal patterns of vegetation in tropical mountains by Alexander von Humboldt. Ritter wished to explain how the destiny of peoples was shaped by the countries they inhabited. Behind these projects, the influence of early nineteenth-century philosophies was obvious. Humboldt stressed the harmony between the different levels of the geographic reality according to the natural philosophies of his time. Ritter followed Herder (1744–1803) when exploring the influence of environment on cultures.

This first type of explanation, linked with the German philosophies of late eighteenth and early nineteenth centuries, was displaced by a natural science perspective when Charles Darwin (1809–82) stressed the role of the environment in the transformation of life. Geographers of the late nineteenth century, Friedrich Ratzel (1844–1904) in Germany and Paul Vidal de la Blache (1845–1918) in France, built human geography on this evolutionist, either Darwinist or neo-Lamarckian, basis. Their ambition was to explain human distributions through the analysis of the mainly 'vertical' (or local) relations people had with their milieu. In fact, they combined the analysis of position inherited from Ritter with an ecological approach. They stressed both the significance of local environments (the ecological approach) and of circulation (the analysis of position). The risk with the ecological approach was to accept a deterministic interpretation of human–nature relationships. Circulation offered a way to escape this danger.

Vidal de la Blache used the idea of *genre de vie* as the main concept of the new approach. In order to exploit an environment, people developed sets of techniques and practices that were soon transformed into a way of life because of the force of habits. The main interest of the *genre de vie* notion was to give a social dimension (the force of habits) to human geography and to stress the role of techniques (either in the fields of production or exchange) in the mediation between human groups and the environment.

Even if Ratzel and Vidal de la Blache were conscious of the significance of circulation, their human geography tried mainly to explain the influence of physical geography on human distributions and the way people took advantage of natural endowments. The role of social relations and of distance as an obstacle to interaction was practically ignored by many of their followers. Human geography was at its best when it used the *genre de vie* paradigm to explain regional structures through the interaction between physical forces and social groups. Unfortunately, this approach could not work in urbanized and industrialized societies, where *genres de vie* became too complex to be a useful means of investigation.

Because human geography was unable to explain satisfactorily the distribution of social groups and artifacts on the surface of the Earth, some geographers, especially in Germany, preferred to define geography as the science of landscape, which avoided splitting the discipline between natural and social parts.

The analysis of position played a central role in the first efforts to investigate political geography. Alfred T. Mahan (1840–1914) and Halford Mackinder (1861–1947) stressed the opposition between inland locations and coastal ones. This theme became central to geopolitical studies in the first half of the twentieth century.

Thanks to the natural sciences, an explanatory dimension had been introduced in geography. Geographers succeeded in organizing efficiently physical systematic disciplines: geomorphology, climatology, biogeography, pedology, hydrology, oceanography, etc. On the human side of the discipline, the results were less impressive. Geographers capitalized more on the analysis of position than on the ecological paradigm. Even cultural geographers like Carl Sauer (1890–1975) did not try to explore systematically the role of techniques in the distribution

of human groups. By the mid-twentieth century, a feeling of dissatisfaction had developed in human geography.

Geography as Explanation: The Social Science Approach

Many geographers tried to give a new start to their discipline. The most successful was Edward Ullman (1912–76). His diagnosis was clear. Human geography failed because it was conceived as a natural science. Overemphasis had been given to the study of human beings–milieu relationships. Circulation, the other face of human geography as defined at the end of the nineteenth century, had been neglected. In order to build a modern geography, emphasis had to be given to social interaction (Ullman, 1980). At the same time Jean Gottmann (1917–95) developed parallel conceptions.

Geographers discovered that economists had developed an interest for spatial economics since the beginning of the nineteenth century. They had explored the influence of distance upon the location of farming, industrial activities, and services. Geographers decided to take advantage of the results of spatial economics to give a more systematic dimension to human geography. It was the basis of the new geography of the late 1950s and 1960s.

In a way, this new geography translated Ritter's position into social terms. Instead of focusing on the opposition between inland and coastal locations, for instance, it focused on the dialectics between center and periphery. The center was defined in terms of social physics as the point or the area that enjoyed the highest accessibility to the totality of a social group. Procedures were invented to measure centrality and to map it. The idea of population or income potential changed the traditional vision. Instead of the center as a point, it presented the center as an area. In the United States, a central core, the manufacturing or industrial belt, appeared as the main feature of the territorial structure.

Geographers relied on spatial economics to develop their new understanding of human geography, but they went far ahead of economists in their analysis of spatial organization. The regional geography of the first half of the twentieth century fell short of a systematic formulation. Thanks to the works of Edward Ullman, Torsten Hägerstrand (1916–2004) and a few other geographers, the way space was organized – through specialization, the development of networks, the dynamics of scale and external economies, and the opposition between center and periphery – became clear.

During the 1970s and 1980s, a few geographers, for instance, Paul Claval (born 1932), tried to extend the analysis of spatial interaction to noneconomic aspects of social life, either social relations or political structures. Instead of focusing on transport costs, they analyzed communication, the structuring influence of commutation costs, the role of medias, and the significance of symbolism. In this way, they provided a new understanding of the dynamics of globalization, so evident from the 1960s.

The emphasis on social interaction had positive effects on geography in many respects, but it reduced the interest in the ecological approach at a time when ecology came really of age and pollution became a major problem at the local, regional, and global levels.

Geography and Postmodernity: The Cultural Approach and the Experience of Nature, Place, and Society

From the early 1970s, a strong critical movement developed in geography. Young colleagues struggled against the conception of their discipline as a natural science and the interpretation that was given to its social dimension. The positivist approach considered social relations as natural facts. It ignored their historical dimensions and their creation through human agency. As a result, neopositivist geographers did not criticize the hierarchical structures and spatial organizations of the groups they observed and explained, even if they were conducive to exploitation and oppression.

From the eighteenth century, a different conception of geography had developed. In his *Géographie politique*, Turgot (1727–81) wished to promote new geographies much more than to explain the existing one (Turgot, 1808–11). It was one of the main features of the geographic projects of the Enlightenment. The critical tradition was represented during the nineteenth century by anarchists like Elisée Reclus and Peter Kropotkin (1842–1921), who made it illustrious, but the prevailing option for a natural science approach restricted their influence.

At the beginning of the 1970s, David Harvey (born 1935) played a decisive role in the development of a new interest for social justice (Harvey, 1973). However, the break with the neopositivist positions of the 1950s and 1960s had other correlates. If social realities are the product of human agency, it is urgent to study the ways people experience places and conceive nature and society, the dreams they have about their future, and the significance they give to their lives. Geographers can no more ignore the ways people organize their existence. The rigid division between vernacular or corporate geographies on the one side, and scientific ones on the other, fades out. Scientific geographers have to explore the geographies of lay people in order to understand the landscape they shape and the institutions they create. Ethnogeography becomes a new field of investigation.

There was an old but limited interest in people's conceptions of place thanks to the analysis of choronyms. The development of new attitudes among geographers had not been possible without the influence of Heidegger (1889–1979). Eric Dardel (1902–68), in France, was well aware of the significance of his philosophy, as Yi-Fu Tuan (born 1930) or Edward Relph (born 1944) a generation later.

When societies are conceived as a product of human activity, i.e., in an historical perspective, it becomes important to understand the practices, attitudes, knowledge, and beliefs shared by social groups, the techniques they master in the fields of material activity and social life, and the significance they give to their lives. The cultural approach, which had been mainly developed by Carl Sauer in the first half of the twentieth century and had experienced a crisis in the 1960s and early 1970s, benefited from a new popularity thanks to Denis Cosgrove (1948–2008), James S. Duncan (born 1945), Joël Bonnemaison (1940–97), and Augustin Berque (born 1942). It was one of the main frontiers in human geography from 1980 onward. Culture ceased to be considered as a collective heritage. It was analyzed as a continuous process of communication, adaptation, evaluation, and refurbishing.

The criticism of the neopositivist conceptions of social sciences was by no means restricted to geography. The transformations of the discipline were parallel with new orientations in sociology, anthropology, and history. Geographers discovered the interest of the Clifford Geertz's type of thick description as a tool to explore ethnogeographies and enter the complexities of cultures.

Under the aegis of French deconstructionist philosophers, Jacques Derrida (1930–2004) and Michel Foucault (1926–84), for instance, social knowledge was increasingly analyzed as a tool to legitimize the Establishment and gain support for governmental policies, whatever their content. Geographers began to scrutinize geographical narratives and look for their hidden significance. They became increasingly aware of the role of geography as an instrument to build efficient forms of social control. Thanks to Derek Gregory (born 1951), the study of geographical imaginations and of their role in social life and power situations became popular (Gregory, 1994).

The new epistemologies are increasingly critical of the great narratives of the past. Geographers are reluctant to rely on macrotheories or philosophies—historical materialism, for instance. They develop a growing interest in the local and privileged micro- or mesotheories. They explore realms that had been previously neglected: gender geography, the geography of young and aged people, the varied forms of segregation, and exclusion or sexual differences that most societies build.

Men and women do not live in a standardized, sterilized, and acclimatized space. They inhabit specific places, develop territorial identities, and use landscape markers as symbols of what unite them and provide them with a sense of shared community. Consequently, geographers are increasingly concerned with the religions, philosophies, or ideologies people create in order to give significance to their lives. They explore the moves the human mind performs in order to discover perspectives of society, nature, and collective destiny, and build values. Transcendence and immanency are wrongly considered as purely philosophical concepts. They have a spatial dimension; geographers have to explore them.

Men and women are part of nature; they live in nature, with nature (Harvey, 1996). The ecological perspective has been completely recovered. Geographers are increasingly involved in the study of the energy and material relations which develop between human beings and their environment, and in the analysis of the attitudes toward nature, the significance given to natural landscape, and the management of planet Earth.

Contemporary geography goes much deeper into the analysis of social and psychological processes than was the case in the 1970s. At the same time, it has become a more critical and modest discipline. For many of the young radicals, scholars have to refrain from building mega-narratives, as in the past. It is better to concentrate on limited problems.

The Coexistence of Perspectives Instead of the Displacement of Paradigms

Kuhn's interpretation of scientific revolutions was very popular among geographers in the 1970s. They considered the new geography of the 1960s as a new paradigm. In fact, the history of geographic thought does not fit well into the Kuhnian model. We have distinguished five traditions, but when a new one appeared, it did not displace the older ones. The interest in location and mapmaking is less central today than in antiquity or modern times, but it is still fundamental to the discipline. Description as an intellectual venture worth pursuing for its own sake has long ceased to be fashionable, but progress in the analytical instruments offered by other natural or social sciences allows for new readings of landscapes and maps, and the discovery of new patterns. It makes geographers aware of new problems.

Geography as a natural science and geography as a positivist social sciences are still alive. They provided geographers with many of the tools they use, the analysis of position both relative to physical factors along Ritter's views, or social distributions according to Ullman's conceptions, and the ecological approach to human beings–milieu relationships. Many colleagues try to develop more performing models of economic or social distributions. The emphasis on communication is a new development of an old curiosity.

When building a periodization of the history of geographic thought, the development, fading out, and renewal of geographical traditions constitute only one component of the whole picture.

Greek geography was born out a Kuhnian revolution, the invention of the grid of meridians and parallels, but its successes came partly from its role as a repository of Greek culture. With the development of empires, first in Alexandria and then in Rome, it became a useful tool for the new bureaucracies because of the maps it produced and the descriptions it provided.

The decline of the classical tradition in the Middle Ages reflected the disappearance of imperial polities in Western Europe and their displacement by feudal structures, which did not involve explicit corporate geographies. Maps were used as symbols of the monarch's power, not as a tool for his or her action. Because of the development of trade from the eleventh century onward, new cartographic and geographic instruments were needed – hence the invention of Portolano charts. In the Arab world where imperial polities played an important role, the fate of medieval geography was far better.

The new phase of development of geography which started from the Renaissance was linked with the rediscovery of Ptolemy and the cartographic perspective, the voyages of discovery, the rise of the modern state with its proto-bureaucracies, and new forms of corporate economic activities. For two centuries, geography remained based on the two perspectives of cartography and regional description.

The eighteenth century was a major turning point. The cartographic limitations disappeared thanks to an easier measure of longitudes. Because of the progress of natural sciences and the birth of social sciences, geographic description improved much and ceased to be problematical. This kind of description necessarily led to an interest in explanation. The transition from premodern to modern forms of geography was a difficult one and lasted for about a century, since it meant a change in the institutionalization of the discipline: from state cartographic services to universities.

The naturalist orientation that was born at the beginning of the nineteenth century prevailed until the mid-twentieth. From

that time, geography became first a neopositivist social science, and then a discipline, partly scientific, partly humanistic, or philosophical, based on human experience and the significance of the human presence on Earth. Institutionalization began once again to change. Geography is increasingly dependent on research institutions and private funding.

Geography offers the intellectual tools that are needed to understand the contemporary acceleration of globalization. It explains why technical uniformity is conducive to new forms of regional organization and does not entail the destruction of all spatial differentiation.

What will be the future of the discipline? As in the past, a part of the specialty fields it nurtured will develop as fully fledged sciences of their own. The technicalities of contemporary physical geographies will deepen the gap between them and human geography. The future of geography as a unitary discipline is perhaps more on the reflective side than on the analytical side of human knowledge.

Critical Approaches and Postmodern and Postcolonial Interpretations of the History of Geographical Thought

During the twentieth century, the history of geographical thought was mainly developed as an Academic enterprise: its aim was to provide geographers with a better interpretation of their discipline than that offered by the oral traditions developed by any group of scholars wishing to give a meaning to their enterprise. It was, in this way, a critical enterprise, but which remained encapsulated in the Western vision of science.

From the 1990s, the history of geographic thought adopted a more critical orientation, which meant a new interest in non-Western traditions, the collusion between Western geographies and imperialism, and the role of gender in the development of the discipline.

During the last generation, this critical dimension was extended in two ways.

1. By the end of the twentieth century, the interest for non-Western forms of geographic thought and non-Academic forms of geographic knowledge began to develop. Keiichi Takeuchi explored, in this way, the introduction in Japan of Western conceptions of geography, but also pictured the Japanese traditional interpretations of the field and the way they influenced – up to a point – the new orientations (Takeuchi, 2000). This kind of study is today popular in many countries, the Muslim World or Latin America: How *altepelt*, the Aztec vision of the city, was incorporated into the corporate geography of Spanish colonial authorities in Mexico, for instance (Fernandez-Christlieb and Garcia Zambrano, 2006)?
2. A new form of critical interpretations of the history of geographic thought appeared at the end of the twentieth century. It tried to renew itself with the critical perspective of the Enlightenment as analyzed by the Frankfort school in the interwar period and after World War II. It took advantage of the ideas developed by Jacques Derrida (1967) on deconstruction, Michel Foucault (1975) on the role of the observing gaze in the building of societies of surveillance, Yves Lacoste (1976) on the military uses of geographic knowledge, and Edward Said on *Orientalism* (1978). These orientations began to influence the history of geographic thought by the early 1990s, as shown by Gregory (1994). Initially, this critical turn mainly stressed the links between Western imperialism, the development of cartography, and Academic geography (Godlewska and Smith, 1994). It focused on the role of the observing gaze – and of cartography, as its main application – in the development of imperial policies (ÓTuathail, 1996; Driver, 2000).

The critical studies are now more diverse. Denis Cosgrove (2001) gave more attention to the building of Western imagination. The significance of exoticism or the gender dimension of geographies is explored. Jean-François Stazsak (2003) showed how, by the end of the nineteenth century, Western countercultures began to reevaluate non-Western civilizations and geographies. Their views influenced the geographical perception of the non-European world developed in already industrialized countries.

In *Civic Geography: Geography in America, 1860–1890*, Karen Morin (2011) offers a good illustration of the new orientations in the study of geographic thought. In a way her book is a classical one: a biography of Charles Daly, who presided over the *American Geographical Society* for 35 years. Its main interest lies in the way she explores the interplay of Daly's conception of geography, the liberal vision of the world he shared with most Americans of the time and the role of the institution he was responsible for.

> For Morin, geography is not just civic but also disciplined, in the Foucauldian sense. For Morin this means telling the story of the dialectic between thought and action: geographical thought and whether it disciplines how people think about the world and act on it. Without the right thought the action cannot take place in the way that it does. In this sense [Morin] is tackling the history of those who 'thought out space' in the words of Foucault (1984: 244).
>
> Crampton, 2012: 539–540

Through the evocation of Daly's role at the head of the *American Geographical Society*, Morin shows how Daly "explicitly promoted a type of commercial geography in Africa" (Morin, 2011: 21). Was gender important in shaping the scientist Daly's conceptions of geography and the action of the *American Geographical Society*? Morin explores this problem.

Such a study is a good example of the new ways to explore the history of geographic thought. It is strongly contextual and shed new light on the relations between vernacular, corporate, and scientific geographies.

Geographies of Food: Politics, Place, Power Reprised

Nick Lewis and Richard Le Heron, School of Environment, University of Auckland, Auckland, New Zealand

© 2015 Elsevier Ltd. All rights reserved.

Abstract

In this article we work from our positionings in geography, Australasia, and our teaching/researching work to lay out a contemporary landscape of agri-food knowledge and knowledge making. It traces our evolving reading of contemporary agri-food knowledge through participation in the globally prominent Australasian Agri-food Research Network, our own research program, and our graduate agri-food class. The article forms a pedagogical and research development resource based on the situatedness of food thinking and politics that issues a call for more enactive forms of food research as the world enters a period of shifting geopolitics, society–nature relations, and food demands in the Anthropocene.

Introduction

Social science explorations of food are set in trajectories of thought and the material and particular contexts that frame the questions asked by researchers. The choices available around food research are always worked out in situated contexts and situated/grounded ways, while the knowledge we build up around them is forged in an interplay between a politics of food and a politics of knowledge about food. The food literature has a history of geographical silences, while also featuring narratives that bring places together. To borrow a phrase from Campbell (2009), food knowledge is always 'from somewhere' despite any efforts that might be made to globalize it. Any exploration of food and its socioecological relations requires a point of entry into the worlds of knowledge and of material events, a site and moment of framing that is itself a political act, and one that unleashes a politics of knowing. This means knowing and knowledge are framed by shifting trajectories and assemblages in knowledge production that are of both their place and their intellectual field. Critical social science contends that such entry points and political projects of knowledge making have transformative aspirations, and demands that its scholars reflect on the genealogy of their knowledge making but also its politics and that they make these matters explicit. The food literature encompasses many political projects of knowing and a diversity of starting points in geographically situated material concerns, theoretical understanding, and cultures of reading and learning knowledge.

Our starting points are three generative experiences of agri-food knowledge production: our University of Auckland graduate course on agri-food relations and practices (see course description (see http://www.env.auckland.ac.nz/en/about/our-postgraduate-courses/pg-geography-courses.html#a25db098d0b5d458d3ed76723fcdae8b)); 20 years of Australasian Agri-Food Research Network (AFRN) conferences from which we have drawn much of our intellectual inspiration (http://afrn.org.au/); and the Biological Economies (BE) research program, which has dominated our recent agri-food research (Lewis et al., 2013; Campbell et al., 2009). These interconnected sources of diverse knowledge allow us to trace trajectories in the literature that define the field from where we practice our research and teaching and from where we interpret literature shifts. Importantly, ours is a scholarship (and a chapter) grounded in geography. When we say 'geography' we refer less to a well-charted disciplinary field or the location and movements of material things and more to a critical disposition to reveal where things are known and done, disturb extant understandings and presumed universalities in knowing, and highlight both territorialized and otherwise networked configurations of knowing and doing. We see territorialized assemblages as technologies of knowledge production and political mobilization. At the same time, we see critical agri-food knowledge making and practice as a commitment to reframing knowledge and practice of things food in particular constituencies and/or to reterritorializing food politics. Our own knowing and doing of agri-food relations is of our place.

At the heart of the article lies our course, 'Future Food and Resilient Biological Economies' (Geog738), run at The University of Auckland since 2008. We engage our students with and trace local and global issues of agri-food from an Auckland setting. Geog738 privileges a particular reading of a set of debates in the social science of food. Each debate has its own disciplinary or transdisciplinary starting points ranging from rural sociology (family farm to financialization), anthropology (food identities, following as methodology), geography (postproductivism and multifunctionality), economic sociology (calculative practices), to rural sociology science technology studies (performativity of food science), political studies (food regimes (FR)), and/or development (food security), health (food and the body), and environmental studies (nature–society relations). Reflecting our 'Northern Antipodean' setting we take particular interest in the agri-food relations of the affluent North, especially supermarket controlled supply relations, the interplay of food, health, and well-being, and alternative food networks (AFNs); the challenges to the productivism of the practices and policying of New Zealand agriculture. Our location, the School of Environment astride the Arts and Science Faculties, means we draw students from Development Studies, Sociology, and Environmental Management and Environmental Science, a rich mix. Students have included permaculture activists, environmental activists, community volunteers, economists, development NGO workers, local and national politicians, alternative agriculture practitioners, health policy

analysts, chemists, and others interested in all of these fields, as well as cultural theory and life science. This architecture of engagement resonates with what many social scientists are now striving to do.

The annual conferences of the AFRN and their themes have given impetus to a distinctive trajectory Australasian agri-food research, from critiques of Australasian leadership of the GATT-supporting Cairns Group to concerns with the demise of the family farm to engagements with organics, AFNs, community economies, urban food provisioning, and food activism in the Pacific and beyond. The involvement of global protagonists from across the disciplines has in part enabled Australasian researchers to be at the forefront of a number of fields. The significance of AFRN's global agency is demonstrated in the 2009 special issue of *Agriculture and Human Values* on FR. Its coeditors, from Australia and New Zealand, and its contributors had been conspicuous participants or key note speakers at AFRN meetings, where much of the critique and refashioning of FR ideas had been thrashed out. An Australasian synthesis articulated the emergence of deepening divides in food production and consumption with the phrasing 'food from somewhere' and 'food from nowhere.'

The intellectual milieu of the AFRN has analyzed new lines of agri-food research in both New Zealand and Australia and fostered a deep critique of the agricultural research establishment and its grip on policy. The BE project has sought to reunderstand New Zealand in its own terms, shifting away from the family farm as a platform for knowing and politics. The aim was to identify novel theoretical and methodological approaches that might allow us to draw on the literature's new lines of flight and to put the political question of 'why' into the shifting configurations of 'who,' 'what,' and 'how' being grasped at in different literature (Lewis and Rosin, 2013). This required a stretch in imagination and geographic reach. Working with food movements, relations, and translations from paddock to 'someone else's' plate, 'someone else's' environment, and 'someone else's' consumption values demands deep consciousness of priorities of others, an appreciation of epistemic barriers to reimagining, and a recognition that doing food differently is transformative of self and collectiveness. Mobilizing the values of others (predominantly urban consumers in other places) to build prosperity in our settings by reshaping our productivist values and approaches is not straightforward.

In the article we turn first to the major shift in the grand currents in agri-food theorizing that has taken place in the last decade or so involving the opening up of the master narrative of FR thinking. We then highlight six distinctive projects in knowledge production that have emerged from the questioning of FR premises, reorientations from material and discursive conditions, and cross-fertilizations of wider social knowledge into the agri-food literature. The final part of the article uses the work of US rural sociologist Michael Carolan to work through one assemblage of these shifts in knowing foodscapes, an assemblage that directs attention to an engaged politics of knowledge production in food, and one that offers a basis for knowing and enacting food futures differently in what is becoming known as the Anthropocene.

Conceptual Reframings of Food Relations

The late twentieth-century food literature has been forced to respond to significant changes in both global and local food relations and food landscapes, and in approaches to knowing the social world in the wider literature. Here we identify the key shifts in food thinking as researchers have brought a diversity of theoretical and methodological approaches to changing material challenges and priorities. In short, the late 1980s dominance of political economy in the guise of FR thinking and development on the one hand, and a politics of the struggling small farmer and food access (the calorie) on the other, has given way diverse conceptual framings used by different researchers in different contexts to address different concerns in different political projects in different parts of the world.

The FR theorists periodized agriculture and food through a political economy critique of capitalism (Campbell and Dixon, 2009; McMichael, 2009). Emphasizing national subjects and spaces, they linked colonial and neocolonial geopolitics to food production and trade, regulation, and the institutions and institutional sites where regulation takes form (Friedmann, 1993, 2000; McMichael, 1992). They placed food and agriculture at the center of tectonic shifts in global political economy, identifying three distinctive and relatively stable periods of global food economy or historical regimes: the colonial-diasporic (pre-World War II), mercantilist industrial (post–World War I), and 'corporate' or 'corporate environmental' (contemporary) (Friedmann, 2005; McMichael, 2005, 2009). FR theorists focused attention on the rules and governance relations at the heart of the coordination of circuits of production, distribution, and capital (Friedmann and McMichael, 1989) and the dialectical tensions between the regime of coordination and shifting strategies of capitalist accumulation (Pritchard, 1998).

The contemporary, 'third' FR is highlighted by the increasing globalization of production and consumption markets and the inter- and intracorporate relations, and state and private regulation that enable corporations to be "geared to the global or regional markets that are replacing national markets" (McMichael, 1992). It identifies the links between broader investment trajectories in and across nations combined with the supportive rhetoric and institutional development of GATT/WTO with farm-level change, the rise of globalizing supply chains, and the concentration of capital in agribusiness. The actual geographies of agriculture and food began to exceed the FR framings and the territorializations they implied, spawning new lines of theoretical and empirical work to match a moving world of food. The dominance of this political economy reading was undermined further by scholarly reactions against structuralism and Marxian *meta*-narratives and the turns to culture, consumption, and microanalyses of governance focused on practices and technologies (Campbell, 2009).

A more diverse literature now deploys different concepts to address a far wider set of themes. Emerging from post-structuralist, humanist, environmentalist, and posthumanist thought, as well as a fracturing of the political economy challenge to the 'globalization' and the emerging corporatist FR, they offer multiple challenges to contemporary food

economy. (The references that follow in this paragraph are drawn from the Geog738 reading list, and therefore a particular disciplinary reading of broader shifts in the literature.) These can be understood as more or less distinctive trajectories that include concerns with consumers, consumption values, food culture, and identity politics in food (Miele, 2006; Jackson, 2010); society–nature relations and the interplay between human and nonhuman actors (Whatmore, 2006; Carolan, 2008a); environmental change, sustainability, and the challenge to productivism from AFNs (Maye et al., 2007; Goodman et al., 2011); science and technology in food (Enticott, 2003; Miele, 2011, 2013); new ethical and moral economies of food (Jackson et al., 2008); food, nutrition, and well-being (Dixon, 2002, 2009); embodied food experiences and food justice; and ethics (Lockie, 2009; Guthman and DuPuis, 2006; Guthman, 2009; DuPuis et al., 2011; Goodman et al., 2010) the changing countryside of amenity migrants and environmental values (Woods, 2007). Political economy interests have also been recomposed and refocused on retailer control, new private orders of regulation, and questions of food security and food sovereignty, financialization (Campbell, 2005; Campbell and Rosin, 2011; Burch and Lawrence, 2013; Edelman, 2014; Clapp, 2014). New efforts to bring political economy to the materialities of social relations in food supply chains (Pritchard, 2013; Pritchard and Connell, 2011), as well as to food questions at the level of the body (Guthman, 2009), have also been made. As we are compiling this list early in 2014, a new political conceptual framing of food issues is emerging under labels like 'urban agriculture' and 'urban food provisioning' (see Morgan, 2013; Blay-Palmer and Donald, 2006), which promises to refocus questions of food on cities and use this rescaling to bring into dialogue critiques of foodscapes in Northern and Southern worlds, and explicitly to draw lessons for the Global North from the Global South.

Four features of this list are notable. First, the foci are distinctive, but are related. They intersect in the nature of the questions addressed, the politics of knowledge production and common methodologies such as critical discourse analysis and following. Taken together, the different approaches reflect a deepening of knowledge production capabilities around the social and reveal the enrichment of food scholarship over the last decade as authors have drawn more widely upon this capability. This in turn suggests renewed potential for a more varied institutional engagement. Second, the different foci have emerged in relation to each other and the changing priorities of global and local food politics. This is a challenging aspect, not least because it is hard to keep up with what is going on elsewhere. Third, as a result of both of these factors, the list must be considered a particular reading, where the categories are conceived and the borders (albeit porous and changing) are drawn for particular tasks. This cannot be a definitive categorization, though studies of food by social scientists have only recently begun to consider what the impossibility of universality might mean. And fourth, FR thinking has in turn been enlivened by the interest in food sovereignty, consumption, and calculative practices, and by other materialities in food supply chains. Here we point to the growing influence of actor network ideas and the determination of food scholars to put these to particular uses in critical and constructive analyses of food materialities (see, for example, Mather, 2014; Miele, 2013). The screening and narrowing work of the once hegemonic FR perspective is being recognized and credibility, legitimacy, and potential of initiatives missed out in FR narratives are being assiduously investigated.

Key Lines of Engagement with Prominent Trajectories of Agri-Food Knowledge Production

The previous section establishes a conceptual appreciation of social science engagements with the foodscape as a set of interrelated explorations of interests in food relations and associated material questions. We now drill down into these explorations using differently scaled and positioned research trajectories focusing on the work of particular authors with whom we have engaged. We use the metaphor of 'a geography' to characterize these programs, so as to emphasize that there is a defining geography to the engagement, the conceptual armory deployed, and the foodscape of interest. Read from the material world to the research approach, there are clearly immediacies in different places to do with food challenges and food politics, as well as political projects of knowledge production, be they responses to ideological commitments, funding regimes, or a gritty material politics of food security or sovereignty (Edelman, 2014; Bernstein, 2014; Agarwal, 2014). The section is intended as a nonhierarchical intervention of illustrative explorations. By this we mean it does not matter where we start but the consequential links arising from 'an ordering' are likely to yield differing reflections.

Hidden Labor Behind All Seasons Food

Joerg Gertel and colleagues work on temporary food labor migration regimes in the Mediterranean (Gertel and Sippel, 2014). This is a hidden face of food affluence – it is a much more gritty and grounded account of the conditions that are gestured to in the later 'following' accounts of Cook and others, conditions that are built up into mesoscale configurations of processes, and actors and their dynamics. The research tracks multiple investment relationalities of nations, regions, corporate, and local food actors which translate into large shifts and movements of people; continued existence of the state and multiple forms of the state; the conditionality of rights in different places, the relations among them and how embodied and differentially righted labor underpins intensive agriculture of the Mediterranean; the aesthetics of food choice and food health in affluent Europe; and the linkages between the material and discursive. The research is closely tied to Gertel's own following of the emergence of these local–regional–global issues – in mesoscale and longitudinal configurations (Gertel, 2005). This non-Anglo work with its German–French–Arabic focus and German-EU funding, grapples explicitly with the difficult questions that transcend national interests.

La via Campesina – Food Sovereignty and a Radicalizing and Expansionary Initiative

This literature comes out of the food movements and non-Anglo Global South, and draws on activist and Latin American understandings of the possibilities and practice of localized politics. It is land tenure, food entitlement, and livelihood based but animated by the activist's sense of urgency, rights, and possibility in contexts where private land owners and investors have commonly escaped state oversight to more fully appropriate the means of survival. Its focus on peasant production has located it stubbornly in smallholder production. This situatedness has given it an autonomous trajectory, but it has also been aligned to a new generation of FR thinking and political economy by the work of McMichael (2008, 2014) and others, many of whom are exploring the value of food sovereignty as a concept that might transcend the politics of La via Campesina (LVC) (see Bernstein, 2014; for example). It is now also being written into Northern urban agricultural activism through the work of RUAF and others in Europe – bringing a politics of food and political practices from the South to the North and a new geography to the activist politics at its base. (Edelman (2014) points out LVC is now headquartered in Zimbabwe, after periods in Honduras and Indonesia.)

Food and Development

Placing food in the extreme complexities and embodied experiences of development has always proven challenging, often too challenging for agri-food researchers in Western settings. Among AFRN researchers and others with whom we have contact the recent work of Kirsten Lyons (2014), Bill Pritchard (Pritchard and Connell, 2011), and Charles Mather (2014) exemplify a diversity of approaches. Mather's work over the years has targeted major food groups in Southern and South Africa, especially dairying, fruit and vegetable, wine and fish, with a view to showing the impacts of market liberalization on farm workers. Like Mather, Pritchard (Pritchard's 2013 "The realities of food aid" TEDxSydney broadcast, is a valuable teaching resource) uses the global commodity chain lens to look at the fairness and ethicality of supermarket procurement practices in farming communities in India. Lyons's concerns are more enactive, emphasizing how to mobilize networks for environmentally responsible food production and teasing out the possibilities of democratic engagement and impacts for smallholder farmers.

Institutional Innovation for Food Security

In contradistinction to the local scale food activist literature, others are bringing the intellectual to activism via a different route – an enactive commitment to building concrete and cooperative institutions collaboratively with community groups and local government. In our work with students we use Morgan et al. (2006) reflection that the distanced oppositional stance of political economy was disabling thoughts and performance of alternative thinking and economies to introduce the current enactive research of both Morgan and Marsden. That is, while a defining contribution to agri-food scholarship at a time when the literature desperately needed efforts to bring post-structuralist ideas into dialogue with political economy, the book was not in itself politically engaged. Its concluding provocations, however, informed Marsden's later Chatham House research initiatives on UK food futures (Marsden, 2013) and are embodied in Kevin Morgan's recent institution-building work on school lunches and food policy councils (Morgan, 2007, 2010, 2013). This work demonstrates the value of 'safe' spaces of relative autonomy in mobilizing and stabilizing hybrid collectivities of institutional and individual actors.

Enacting Difference from Knowing Difference

A distinctive program of agri-food research in the 2000s coalesced around detailed empirical exploration of alternative food projects, networks, and practices. In the most obvious expression Maye et al. (2007) showed multiple projects: vegetarianism, local food, slow food, and so on. Located firmly in northern settings, the research focused attention on the multiple politics of alterity. As with the later, similarly themed book (Goodman et al., 2011), Maye and colleagues dance between celebrating a politics of alterity in food production and provisioning and a critique of its partialities (class, geographical, and other), and between focusing on the overlaps between different projects and their contradictions – animated by alterity. The two volumes move well beyond farmers markets and the consumption preferences of young middle class professionals in the United States and European cities to enable a connection between discourses of environmental sustainability and more socioeconomically inspired political projects around food. The multiple chapters in the earlier volume expose a rich variety of place-based initiatives and systematic research, thereby not only celebrating diversity but empowering its enactment. The work established a potential bridge to that of the Australasian inspired Community Economies project (Gibson-Graham, 2008; Cameron et al., 2013) and its particular grounded politics of alterity.

Following as a Methodological Intervention

The landmark paper of Ian Cook (2004), "Follow the thing: Papaya," unhinged many traditions in agri-food research. Distinguished by its lack of formalism, it became the first in a series of papers that pressed open inquiry into consumption-end ethics and moral economy, and implicitly traversed the 'who-what-how-where-why-when' landscape that we see as so vital in future work (Lewis and Rosin, 2013). Most powerfully it signaled overt commitment to exploring practice and micromaterialities, as well as discourses; borrowing from the anthropological gaze and thereby ethnography and practice-centered notions of identity and culture; innovation around performing, journeying, and motion in both foods and text; and thus in relating practices of knowing and materiality. The trilogy carried by *Progress in*

Human Geography (Cook et al., 2011) is startlingly different in their experimental exploration of methodologies of knowledge making. The trajectory brings consumption, its ethics, aesthetics, and its politics onto the stage, together with anxieties over the other and the hands that grew their food. It does so in a socialized form and while it tends to be about individual engagement it provides a language and a sensitivity to/of identity and subject formation around food which is not present in any other of the literature that we study – albeit focused on the affluent consumer. Others working back toward the consumer from production places through distribution and regulatory networks have also deployed a cultural political economy that deploys techniques of following (see, for example, Freidberg, 2004; Jackson, 2010).

Healthy Gendered Foodscapes

Domestic foodscapes and food and health meet in the research of Jane Dixon. The basic questions of equity and human dignity presuppose an enactive disposition (Olsen et al., 2009). This has been important for our students. Dixon takes her work to the heart of the political economy of health (Dixon, 2009), but from very situated positions (Dixon and Banwell, 2004; Dixon and Isaacs, 2013). Her work points to the lively materialities of intrabody engagements with food and the way the materialities are so tightly interwoven with the major questions of political economy. This takes us beyond the fetishization of calories because of the framings she employs. Her work considers how corporate strategy, government policy, and civil society in countries, such as China, Thailand, and Australia influence cultural transitions in food. When Jane visited the University of Auckland in 2009, she encountered both the warmth and earnestness of a postgraduate class dedicated to questioning food and the critical ambivalence of more mainstream health researchers elsewhere in the university to her work.

Reassembling How We Know Foodscapes: An Ontological Politics

These particular projects of knowledge production and their food politics are necessarily partial, situated, and incomplete with respect to incorporating the shifts discussed earlier in the article. In 2006, as this richness of conceptual reframing was coming into view, Morgan et al. (2006) challenged agri-food social scientists to articulate their interests and approaches to what they called 'worlds of food' around a clear politics and a rethinking of power, place, and provenance. They had begun to reassemble insights drawn from different intellectual traditions (actor network approaches, FR thinking, local food activism, and institutional engagement with food actors). The response to the underlying challenge that we emphasize here is that crafted by rural sociologist Michael Carolan, whose own project of reassemblage of thinking about food politics coincided with the 'Worlds of Food' intervention (Carolan, 2006). Carolan has a privileged place in our entry points, having been a highly valued guest of the BE project (Carolan, 2013b) and having spoken as a guest lecturer to one iteration of the Geog738 class.

Carolan's work has brought new insights from environmental politics and post-structural thinking to the food literature (Carolan, 2004, 2006, 2008b, 2009), but from within the grounded traditions of North American rural sociology. He recognizes the crucial place of representing the real, but as a preliminary to informing and moving into ways to perform food worlds differently. In doing so it has taken seriously the invocation of 'who, what, how, where, why, when' in making food knowledge and of enactive research (Carolan, 2013b). This has led to books that break the convenient canons that detune people from the realities of the contemporary world. Grouped, his writings are an intellectual expose on questions such as the real cost of cheap food and the embodied nature of food politics. His work has asked why is 'who' so important a question when it comes to the production of food knowledge (both who is representing foodscapes and who is living them), and offers a humanist moral project around the quality of food. These framings have destabilized taken for granted ontological positions and politics alike, but more in the traditions of an engaged sociology of food than the deconstructionist tradition of cultural theory.

Carolan's *Reclaiming Food Security* (2013c), for example, fundamentally reworks the terrain of food security discussion by introducing the Food and Human Security Index (FHSI). An FHSI score is calculated for 126 countries based on indicators of objective and subjective well-being, nutrition, ecological sustainability, food dependency, and food system market concentration. The final FHSI ranking produces many counterintuitive results. As he notes, why, for example, does Costa Rica top the ranking, while the United States comes in at number 55? The question is a highly political question that connects with the work of food researcher–activists who highlight food inequalities such as food desserts.

Carolan's book is an invitation to do several things: work with demonstrable objects of comparison, including where appropriate with numbers; engage in food knowledge in experimental ways so fracturing existing modes of analysis and framing (Le Heron, 2013); and politicize food by revealing and challenging assumptions and myths. His latest book (Carolan, 2014a) *Cheaponomics: The High Cost of Low Prices* takes aim at the false economy of cheap food and makes available a politics for alternative food movements to bridge the gap to wider audiences and dispel myths that they are out of touch and range of food security questions. In other recent work (Carolan, 2014b), he attempts to shift the discourse of individual level responsibility and commitment from food consumer to food citizen, a project that parallels some of the recent shifts in food sovereignty thinking. For us his work is that of a knowledge activist, translating critical and alternative ideas into coherent and cohesive knowledge projects beyond the academic and research communities, rather than being a political activist of food like Tim Lang (2013) or Raj Patel (2007). In each case, the knowledge they produce about food draws on their situatedness. Lang is deep in the UK and global policy circles, Patel has both worked at the World Bank and protested against it, while Carolan reaches to his theoretical work.

This politics of performative knowledge making adds new purchase to the moral economies of and suggestive politics of

Embodied Food Politics and begins to turn the technologies of control in the new materialities of FR back on power. It is informed, by a politics of social and environmental justice that owes much to shifts in understandings of nature–society relations, the food imperatives of environmental change, the embodied nature of food relations, health, and nutrition, and epistemological demands of post-structuralist ontologies. And in very interesting ways it is mirrored by the recent engagements of Terry Marsden with institutional actors and those of Kevin Morgan with local food activists.

Conclusion

This article emphasizes the inescapable situatedness to the social science of food, and is written to highlight that this must be acknowledged even in an encyclopedia article. Depending upon where you start you will see different things. This is a reality of the politics of place and its representation, the making of relevance, funding materialities, meaningful teaching resources, and the more mundane performativities of institutional setting, publication, and career building. This is how a body of literature is (and must be) built up, such that knowledge making, knowing, and knowledge as text or practice is always situated. In Geog738, our own reading of the different literature and efforts to draw meanings and linkages across them, the reaction of our students to them, and the different ways in which the students have assembled the trajectories in the literature, their own projects, and their association of the literature to material worlds, renders social knowledge of agri-food inherently situated both in its making and its refashioning through learning. The AFRN has nurtured particular place-centric intellectual development, while BE has taken us into enactive research, assemblage of provenance, and experimentation, all of which we are now writing into the agri-food literature. There are myriad agri-food projects, many with radical new lines of inquiry, multiple food courses all with their particular privilegings and relevances, and there are likely other food research networks existing at some kind of level in other places. Our reading and this encyclopedia cannot be the only, the most authoritative, or the final word.

In the politics of food, the challenges of 'what next' in the Anthropocene appear almost overwhelming. There are new imperatives for, and questions of, food safety, security, and sovereignty. Food, energy, and water are positioned at an interconnected core, which we are poorly equipped to address. Place-based food initiatives are contesting the 'who, what, why, and how' of putting food into mouths in place. Community economies and other urban agriculture initiatives offer some hope, as do the renewal of AFNs despite 'cheaponomics' and intensifying pressures on household food budgets, and efforts to link AFN concerns with the practices and possibilities of alterity to via campesina-like concerns with smallholder and collectivized models of agricultural production (Martínez-Torres and Rosset, 2014). This is not to deny political economy, the dominance of corporate FR realities, and the emergence of new forms of 'not food' (be these nonfood products or monster foods). Rather it is to trouble and disrupt them and as Carolan (2013c) observes, to search for new ways of putting the 'alter' into alternative foods.

Taking food as a lens seriously is what we ask our students to do. The article contends we can only do this in situated conditions and our gaze is situated. Partly following from this, every social science discipline offers significant insight. Food research agendas can only be situated, despite the appearance of universal research agendas. What we have shown throughout the article is that there are many initiatives but few connections. We have not talked about pedagogy per se but we have centered the article on situated learning. When interrogated we find situatedness in place is the 'where-when' of living food, a crucial but often forgotten domain of the nature of knowing and of knowledge making and fundamentally related to 'why' we might act to know, what it exists to be known, and how we might come to know. In worlds of food place becomes the site of the actualities of politics and power as agency configures 'who, why, what, how' relations affecting food. This is the insight that Michael Carolan (2004, 2006) harnesses when he speaks of epistemological distances and their disabling influences. Cartesian mappings and distance are always an unacknowledged cartography of situated knowledge production of food. The challenge in the twenty-first century is to connect our way out of the entrapments of a Cartesian mind frame and instead map hopefulness into the realities of fair food for all in places.

Geography: Overview

Ron Johnston, University of Bristol, Bristol, UK

Abstract

The practice of geography – literally 'earth writing,' from the Greek *geo* and *graphein* – extends back at least 2000 years, but it has a much shorter history as an academic discipline, with little formal presence in either universities or schools before the twentieth century. Its key concepts are environment, place, scale, and space and it seeks to understand not only what is where, and why, but also how people experience, and behave in, different places, and why. Although most definitions (and university departments) of geography embrace both human and physical worlds, studies of human and physical geography are now substantially separate components of the discipline. In any period, the nature of geography and geographical practices – what it studies, how and why – is conditioned by the contexts of time and place. Geography emerged as an academic discipline just over a century ago out of a subject that had long been practiced without formal institutionalization in universities. Its evolution since then has passed through various stages as its practitioners respond to society's needs – in all levels of education, and in fundamental and applied research, for example. Geographers seek not only to understand the earth and its human occupance but also to improve it.

The practice of geography – literally 'earth writing,' from the Greek *geo* and *graphein* – extends back at least 2000 years, but it has a much shorter history as an academic discipline, with little formal presence in either universities or schools before the twentieth century. There have been many attempts to define it: one widely used in the mid-twentieth century saw it "concerned to provide accurate, orderly, and rational description and interpretation of the variable character of the Earth surface" (Hartshorne, 1939: p. 21) but its focus is now much wider. Its key concepts are environment, place, scale, and space and it seeks to understand not only what is where, and why, but also how people experience, and behave in, different places, and why.

Although most definitions (and university departments) of geography embrace both human and physical worlds, studies of human and physical geography are now substantially separate components of the discipline. This article focuses on human geography, that part normally affiliated with the social sciences and the humanities, while recognizing a recent partial coming together of the two sections, reflecting not only contemporary concerns with environmental change, its causes and impacts, but also the realization that separating humans and nature creates a false dichotomy – each is a part of the other (Whatmore, 2002).

In any period, the nature of geography and geographical practices – what it studies, how and why – is, like that of many other disciplines, conditioned by the contexts of time and place. Thus, as outlined here, geography emerged as an academic discipline just over a century ago out of a subject that had long been practiced without formal institutionalization in universities. Its evolution since then has passed through various stages as its practitioners respond to society's needs – in all levels of education, and in fundamental and applied research, for example. Geographers seek not only to understand the earth and its human occupance but also to improve it.

Intellectual Origins

As a source of information about the earth, geography has been practiced in all societies – if not always by that name. In most of them, creating and storing locational information involved some form of cartography, as the multivolume history of cartography project is revealing (Harley and Woodward, 1987). Mapmaking was part of the geography taught at Cambridge and Oxford universities in the late sixteenth century, for example (Cormack, 1997), and, along with map interpretation, was central to most degree curricula until well into the twentieth century. A second major strand of early geographical education was chorology, description of different physical environments and their inhabitants. Geographers portrayed the rich mosaic of world regions – large and small – to meet the needs of traders, diplomats, and the military as well as whet the curiosity of the 'educated classes.' Much of this development of the subject was closely linked to imperial projects – both formal, through colonization, and informal (Driver, 1998; Kearns, 2009; Morin, 2011) – and many university geography departments were established in British Commonwealth countries during the twentieth century.

In the early- and mid-nineteenth century geographical societies were founded in European and North American cities to promote geography, in particular exploration (Livingstone, 1992; Bell et al., 1995), and its commercial applications (Chisholm, 1885). Some societies later actively promoted geographical education: in the United Kingdom, for example, the Royal Geographical Society realized that geography could only be successfully introduced as a school subject if it was first established as a separate academic discipline in the country's ancient universities, where it funded some of the first appointments of geographers (Stoddart, 1986).

Preceding the British developments, the first university chairs and departments in the new discipline were established by royal decree in Germany in the 1870s: the departments were to prepare school teachers, as part of the creation of an educated citizenry, and sustain colonial and military enterprises. (The first established chair in the Netherlands was explicitly created in 'colonial geography.') In the United Kingdom, the first separate honors degree in geography was only established in 1917 – at Liverpool. The British departments then were small, with few teaching staff (for whom research was not a priority) and students – most of whom

became secondary (mainly grammar) school teachers after graduation. Virtually every UK university had a separate department of geography by 1950, however, and they formed the foundations for major expansion thereafter (Johnston and Williams, 2003). There were parallel developments in the United States, except that geography never gained a substantial presence in high school curricula there (Schulten, 2001).

Creation of a Discipline

The subject matter taught in these new departments focused on people–environment interrelations, as conceived by several pioneering German and French geographers. Among them, the early works of, for example, Varenius (Mayhew, 2010) and Kant (see May 1970; Harvey, 2009; Elden and Mendieta, 2011), followed in the nineteenth century by Hettner (see Hartshorne, 1939: Harvey and Wardenga, 2006), Humboldt (1845–1972; see Bowen, 1981), Ritter (1817–1859; Linke, 1981), Ratzel (1882–1891), and Vidal de la Blache (1903; Buttimer, 1971) became disciplinary canons. Some of these pioneers' followers promoted their ideas oversimplistically (such as the environmental determinism advanced by one of Ratzel's American disciples, Ellen Churchill Semple, 1911 – see Keighren, 2010) but most portrayed geography's subject matter as the myriad ways in which the nature–society interactions created different landscapes (as Mackinder – the first appointed geographer at the University of Oxford – defined the discipline in 1887; his definition was paralleled by US contemporaries – e.g., Davis, 1909).

According to Freeman (1961), up to the 1950s geography was characterized by six separate but linked concerns: encyclopedic, colonial, educational, political, generalizing, and specialization. Subsequently, the first two continued their long-term decline (exploration of terrae incognitae by European societies had reached its near-conclusion and decolonization was rapid) and the last two came to dominate: the educational and political components changed to reflect these shifts. The emerging practices were strongly influenced by their national and local milieux (Livingstone, 1992; Livingstone and Withers, 2011), but for a few mid-twentieth-century decades the disciplinary core was widely identified as the study of regions, relatively homogeneous segments of the earth's surface defined on criteria reflecting the natural environment and its modification by humans. In the United States, Hartshorne (1939: p. 462) presented geography as

> … a science that interprets the realities of areal differentiation of the world as they are found, not only in terms of the differences in certain things from place to place, but also in terms of the total combination of phenomena in each place, different from those at every other place.

Regions are unique areas, and so, according to a British geographer (Wooldridge, 1956: p. 53), regional geography – promoted 25 years later as 'the highest form of the geographer's art' (Hart, 1982) – aimed

> … to gather up the disparate strands of the systematic studies, the geographical aspects of other disciplines, into a coherent and focused unity, to see nature and nurture, physique and personality as closely related and inter-dependent elements in specific regions.

This identifies two long-recognized strands in geographical practice (stemming from the writings of Humboldt and Ritter respectively): the systematic – focusing on particular subject matter – and the regional, synthesizing material on specific areas (at varying scales). The European roots weakened after 1945, however (Johnston and Claval, 1984), and a specific Anglo-American discipline emerged (albeit not without national differences: Johnston and Sidaway, 2004): 'Anglo' dominance is now the subject of considerable contemporary criticism in other language realms – although in some of them (the Scandinavian countries and the Netherlands being the main examples) English is now the dominant language in geographical research and, increasingly, teaching too (Johnston and Sidaway, 2015).

A 'New' Geography

Systematic specialization increasingly dominated the expanding academic discipline from 1950 on, involving two intradisciplinary divides: a split between physical and human geography, reflecting their growing links to the natural and social sciences respectively; and the creation of separate specialisms within each. Regional geography declined rapidly as a subfield, although some scholars continued to maintain the importance of each geographer becoming an expert on a specific (usually 'foreign') part of the world (Mead, 1963); by the century's end it was only a minuscule segment of the discipline. Individual human geographers increasingly defined themselves by their systematic specialisms: historical geography, led by Darby (2002), was (and remains) especially strong in the United Kingdom, as was cultural geography – led by Sauer (1952), with strong links to anthropology – in the United States. Economic, political, and social geography were small enterprises until the century's last quarter.

The 1950s/1960s were characterized by the discipline's so-called 'quantitative and theoretical revolutions' (Burton, 1962). These involved both human and physical geography, leading to a brief period of intradisciplinary collaboration focused on methods. Among human geographers, the focus was the identification of spatial order in human occupance of the earth's surface, rather than a concentration on the unique characteristics of individual regions. Schaefer (1952) was among the first to promote geography as a spatial science, a nomothetic (as against an ideographic) orientation that placed the discipline within the burgeoning – quantitatively oriented – social sciences, whose findings were having an increasing impact on public policies. The 'revolutions' involved embracing a particular form of scientific method (positivism) that was theory-led and involved the application of quantitative methods to test hypotheses and draw general (lawlike?) conclusions (Harvey, 1969; Amedeo and Golledge, 1975). Geography's niche within the social sciences was to be location theory, and its identifying rationale a focus on space as an influence on (determinant of) individual and collective behavior; geography was to be a 'discipline in distance' with geometry the key mathematical stimulus (Bunge, 1966; see also

Sack, 1981). Space was usually interpreted as the cost involved in the movement of goods, people and information, and classic theories – most initiated outwith geography – of land use patterns (von Thünen: Chisholm, 1962; Hall, 1966), central places (Christaller, 1966), industrial location (Smith, 1981), and gravity models (Olsson, 1965), for example – were appropriated as the foundations for this 'new geography'; statistical modeling was adopted as the means for hypothesis-testing to identify general patterns in observed geographies.

The 'revolutions' were initially North American in provenance, rapidly spreading from a few innovation centers (Johnston and Sidaway, 2015), but soon infiltrated British geography, notably through two seminal anthologies (Chorley and Haggett, 1965, 1967). Further spatial theories were added – particularly the spatial diffusion of innovations (Hägerstrand, 1968) – and the entire corpus synthesized in influential textbooks (notably Haggett, 1965; Abler et al., 1971) which covered the relevant theories and their empirical explication plus the methods to be deployed in spatial analysis. Within those general frameworks, systematic specialisms rapidly emerged, initially in economic and urban geography, within each of which separate, overlapping, sub-subdisciplines were formed: economic geography spawned industrial, agricultural, transport, and development geographies, for example: urban geography begat a substantial urban social geography and was paralleled by increased interest in rural geography; out of social geography emerged both population and medical (later health) geographies; and a revived political geography incorporated electoral geography. By the late 1970s these various disciplinary components achieved institutional status through the creation of specialist groups operating within the overall umbrella of the major learned societies, such as the Association of American Geographers and the Institute of British Geographers; the groups held their own conferences and sessions within larger meetings, and published their own journals alongside the longer-established generalist serials.

This burgeoning activity was possible because the discipline was expanding rapidly within universities in response to increased student demand. The revolutions' promoters achieved major intradisciplinary change within a relatively short time by portraying spatial science as filling contemporary gaps within the social sciences, while at the same time criticizing, even denigrating, both regional geography and those parts of the discipline which failed to be converted to the new ways (Johnston, 2006).

'-isms,' 'Schisms,' and 'Turns'

Although some promoted this 'new geography' as surpassing its predecessor, there was no complete revolution to a new hegemonic paradigm in Kuhnian terms. Some geographers continued to teach and research in their established ways, sustaining the traditions of historical, cultural, and (to a lesser extent) regional geography. More importantly, spatial science was soon the subject of two main criticisms. The first attacked the narrow economism of location theories which privileged profit-maximizing (expressed in geographical terms as transport-cost-minimizing) as a determinant of decision-making, thereby (at least implicitly) denigrating the wide range of other cultural influences on behavior. Spatial science, it was argued, assumed that individuals respond to stimuli in predetermined ways, and the elevation of space as a predominant influence led to a derogation of place – the context of so much human learning – and the importance of human free will. Some critics explored alternative philosophies to positivism – such as phenomenology, idealism, and existentialism – in work characterized as humanistic geography which emphasized the variety of human decision-making criteria and behaviors. Although those alternatives attracted few permanent adherents, they presaged an exploration of a much wider range of approaches to social theory (Jackson and Smith, 1984). This became known as geography's 'cultural turn'; it was not a return to Sauerian cultural geography and its emphasis on landscapes, however, but a new focus on the contingent nature of much individual and group behavior – with much of that contingency being place-based. It involved greater interaction with not only other social sciences but also the humanities, within which a greater appreciation of the role of places as crucial contextual locales led, in turn, to a 'geographical or spatial turn' within some of those disciplines.

The second set of criticisms concerned spatial science's approach to explanation. Location theories, it was argued, could not account for the major contours of the geographies of development and underdevelopment at various scales, of inequality and injustice, wealth, power, disadvantage, and discrimination: the theories were apolitical and could not be used to achieve fundamental change in an inherently unequal socioeconomic mode of production. Explaining those geographies required an appreciation of how economic systems – especially capitalism – operate. A major stimulus to such arguments was Marxism, notably through Harvey's (1973) provocative essays, which presaged a series of seminal volumes building a historical materialist geography (e.g., Harvey, 1982, 1996). This body of work became known as radical geography, which spawned its own journal – *Antipode*. Not all who accepted the critique's key arguments were prepared to adopt the Marxist political program, but the shift to studying capitalism as a system stimulated work in (spatial) political economy more generally, which became a major focus of work in economic geography.

Both critiques of spatial science attracted adherents, but others expressed dissatisfaction with the alternatives. As Gregory (1978) argued, whereas some spatial science strayed very close to naive economic determinism, some humanistic geography approached another extreme – of voluntarism, tearing the individual out of context; meanwhile, some radical geography offered little more than an alternative economic determinism. But those three broad approaches – spatial science, radical-structuralism, and humanistic geography – became the cores of much debate over subsequent decades as the discipline divided – if not fractured – into increasingly separate, sometimes antagonistic, components.

The Contemporary Discipline

Sheppard (1995) divided human geographers into two main groups – spatial scientists and social theorists. Although each – especially the second – embraces a wide range of subject matter and approaches to the discipline, nevertheless that binary

divide encapsulates the two major strands of contemporary scholarship, characterized, among other ways, by their separate methodological foundations – quantitative and qualitative, respectively. Such is the divide between them that few introductory human geography textbooks now fully cover both and some either explicitly dismiss spatial science as part of a 'discredited past' (Peet, 1998) or simply ignore it (e.g., Cloke et al., 1999): against that, US volumes promoting the discipline to the national scientific research community focus almost entirely on spatial science (NRC, 1997, 2010). Some encyclopedia (e.g., Kitchin and Thrift, 2009) and dictionaries (e.g., Gregory et al., 2009) are more all-embracing but attempts at comprehensive overviews lack integration (e.g., Gaile and Willmott, 1989, 2001) and the editors of a volume on the "pervasive themes [and] common elements within a discipline whose practitioners are in danger of forgetting their shared heritage and ideals" concluded presciently that not only had they failed to bridge the human–physical divide but they also feared a similar split opening up within human geography (Abler et al., 1992). One popular text – which appeared in several editions – did successfully combine perspectives from human and physical geography, though most of the material from the former was of the spatial science variety (Haggett, 1972, 1990).

Spatial Science

Spatial science remains a substantial minority component of contemporary human geography, but its orientation has changed considerably over the last half-century. It is strongly, and increasingly sophisticatedly, quantitative but the formal (geometrical) location theories based on a single causal variable (distance) have largely been abandoned: the search for spatial order neither anticipates the discovery of regular patterns in the landscape nor seeks universal laws of human spatial behavior. Space has been replaced by place as the key underpinning geographical concept – increasingly recognizing its multiple scales. Sayer (1984) drew an important distinction between extensive and intensive research: the former seeks empirical regularities whereas the latter explores the causal chains responsible for particular outcomes. Much spatial science is extensive, a necessary precursor to later intensive investigations: by not eschewing empirical generalizations it identifies significant features and trends in the mass of numerical data that characterize modern societies. An underpinning assumption of much of the research in this mold is that as nonexperimental disciplines the social sciences cannot establish causality in the same way as the natural and some of the environmental sciences: what matters is the quality of the theory underpinning the empirical investigations: "Causal inference resides at a theoretical level and is not something that comes directly from the data" (Sampson, 2011: p. 380).

Geographers in the 1950s to 1970s assumed that standard statistical procedures could be applied unproblematically to the analysis of point, line, flow, and areal data. This was challenged by work on two particular technical areas:

- spatial autocorrelation: particular features of spatial data encapsulated in Tobler's first law of geography – "Everything is related to everything else, but near things are more related than distant things": Sui et al. (2004) require bespoke analytical procedures to produce valid results (Cliff and Ord, 1973); and
- the modifiable areal unit problem which showed that scale and aggregation effects both substantially impact on the results of analyses of areal data (such as population characteristics) of small areas: Openshaw (1984) demonstrated that different aggregations of small areas into larger blocks can produce divergent statistical results – a finding applied in Gudgin and Taylor's (1979) pioneering modeling of the impact of different districting schemes on election outcomes.

Building on these foundations, geographers developed a range of 'local statistical methods' to identify significant spatial patterns (Anselin, 1988), and adapted other methods – such as multilevel modeling (Jones, 1991), which integrates local variations and autocorrelation at a variety of spatial scales.

These increasingly sophisticated changes in spatial science were facilitated by – indeed would have been impossible without – developments in computing power, stimulating the conception of geocomputation to encompass such work in both human and physical geography (Longley et al., 1998); there is an annual international geocomputation conference and a National Centre for Geocomputation has been established at the National University of Ireland, Maynooth. More powerful and faster computers allowed analysis of increasingly large and complex data sets – including those generated through remote sensing. The most significant developments were in geographical information systems (GIS), combined hardware and software for the organization, integration, analysis, and display of spatially referenced data, with the display media underpinning the growth of visualization strategies and the rapid production of maps and diagrams: the satellite and keyboard have replaced the field and drawing board in cartography. Alongside their widespread research use, GIS have underpinned a range of commercial applications, and their development has led to the identification of a geographical information science (Goodchild, 1992). Their application has stimulated many teaching programs providing graduates with skills relevant to a range of potential careers (NRC, 1997, 2010): many textbooks (e.g., Longley et al., 2005) serve those audiences and geography/ers are at the core of a substantial service industry.

Social Theory

Although spatial science remains a substantial and vibrant component of contemporary human geography, to many the approaches grouped together under the 'social theory' heading now form the disciplinary mainstream (e.g., Massey et al., 1999). Humanistic and radical geographies have metamorphosed into new forms – although some maintain allegiance to the original formulations, as in Harvey's (2005a) continued reworking of Marxist theories in contemporary contexts.

As in spatial science, place (rather than space: Taylor, 1999; discusses the tensions between the two) and scale are the key underpinning concepts: places are the milieux within which

differences are produced and reproduced, within which people learn, act, and influence others. But places are not fixed containers: they too are produced and continually reproduced yet changed through human action. In studying people–place interactions, geographers were influenced by Giddens' (1977) concept of structuration: each is continually transforming the other – people make their own histories but within spatial contexts that are both constraining and enabling. (Giddens',1984 – work was an early example of the 'spatial turn' in the other social sciences, influenced by Hägerstrand's, 1982 – time geography, which drew attention to the geographical constraints on how individuals pursue their personal and collective projects.)

A very important stimulus to appreciating the role of milieu/locale in the structuration of difference came from feminist geography. Initially launched in the 1980s to highlight discrimination against women within a male-dominated and male-oriented discipline, and the consequent silences in what geographers studied, this extended into a much wider critique of 'single-factor' approaches, such as Marxists' concentration on class and the economic infrastructure that ignored other important social cleavages (Women and Geography Study group, 1984, 1997; Rose, 1993). People socialized into, and viewing society from, different positions create separate identities of self and other, which are potential foundations for identity politics. The class struggle is not the only cleavage within capitalist society and others (based on not only sex but also race, religion, and sexual orientation, for example) cannot be folded within it. Indeed, these various cleavages interact; a realization emerged within feminist geography, for example, that women's identity politics in more 'developed' countries differed from their contemporaries' in excolonies.

Other stimuli came from postmodernism, which also emphasized difference and rejected the search for grand theories. Soja (1989) and Dear (1998) introduced it to geographers as a way of addressing the argued transition from a Fordist regime of accumulation characterized by production of uniform commodities for mass consumption to post-Fordism and its small niche markets with consumption for status as well as use – sometimes termed flexible accumulation – in which tastes changed frequently, reflecting local concerns and influences.

More important have been impulses from post-structuralist arguments that human subjectivity is not pregiven but rather produced in contexts: geographers have argued that those contexts are necessarily spatially and temporally contingent, so that concepts of truth and knowledge are too. Representation of these contingencies is crucial to social conduct, and post-structuralists stress the importance of language not only as a communication medium but also as a social construction itself (as in the relationships between signified and signifier and their interpersonal transmission through hermeneutics). Language is only one means of representation and communication, however, and alongside the interpretation of written texts geographers have focused on other images – works of art, maps, and landscapes – implicated in the production of situated knowledges (Barnes and Duncan, 1992; Cosgrove, 1998). But not all events and interactions are recorded let alone 'archived' for later analysis: much transitory but meaningful spatial behavior goes unrecorded, and analysis of such practices has led geographers into nonrepresentational theory and studies of performativity (Thrift, 2007).

Whereas much of the work stimulated within human geography's 'cultural turn' focuses on the individual condition and small scale events, including the body as a site of identity-formation (the most intimate of 'personal spaces' – or 'the geography closest in': Pile, 1996), there have also been changes in larger-scale concerns. Work in geopolitics, for example, has been much influenced by Said's (1978) Orientalism – the West's creation of a 'mythical East' – as a stimulus to investigations of the role of images of places and their peoples and, as illustrated by Gregory's (2004) book on Afghanistan, Iraq, and Israel–Palestine, their influence on political actions. Territory and territoriality are key in the spatial construction of these geographies (Sack, 1986; Elden, 2009, 2013), which embrace postcolonial movements that challenge not only the economic and political components of colonialism and imperialism (and geographers' participation therein – Smith, 2003; Morin, 2011) but also their roles in creating imaginative geographies at variance with those of people who experienced that external power: the latter are now creating their own alternative imaginative geographies, knowledges, and identities which articulate their desires, fantasies, and fears. As Harvey (2005b) argued, there is a myriad geographical imaginations, created worlds which people not only occupy but also portray to others: 'professional' geographers are not the only creators and purveyors of geographies – the editors of popular geography magazines present the world in different ways, as do travel agents and film/TV producers.

Geography in Action

Many geographers have long put their knowledge and expertise to use beyond the research laboratory and library in what has been generally termed 'applied geography.' After the 'age of exploration' had passed, geographers' skills in mapping and regional synthesis were promoted as valuable foundations for spatial planning, and this continued with the claimed utility of spatial science to, for example, identify optimal locations for shopping centers and transport links. From the late twentieth century on major changes in the political environment within which universities operated involved increased pressure to undertake research which had applied value to both the state apparatus and, particularly, private sector 'wealth creators' (Breheny, 1989).

One area of geography which this growing emphasis on applied work stimulated was GIS, presented as a key set of tools that geographers could apply and transferable skills that they could inculcate in their students (NRC, 1997). Some of the applications continue to advance the 'geometrical' approach to spatial science and the optimal location of facilities (Birkin et al., 2010); others illustrate the turn to place-based analyses – in geodemographics, for example, the classification of small areas according to their population characteristics to facilitate targeting of potential consumers for particular goods and services (Harris et al., 2005). Early critiques of GIS argued that they were readily implicated in the exercise of both commercial and geopolitical power (Pickles, 1995), a trend since partially countered by the development of 'participatory

GIS,' intended to equalize access to the relevant resources (Elwood, 2006), and 'neogeography,' which provides online tools to enable mapmaking by nonprofessionals (Goodchild, 2009). Many GIS applications involve human–environment interactions, such as changes in land cover, the management of physical resources, environmental changes, and risk analyses. These involve more contact between human and physical geographers than characterized previous decades (Pappenberger et al., 2012; Landstrom et al., 2011) but are largely separate from the growing interest in wider issues regarding nature (Castree, 2005; Whatmore, 2002). Much of the work undertaken for private sector sponsors is not published in academic journals for commercial reasons, but papers on environmental management and optimal locational decision-making dominate the journal *Applied Geography*.

Outwith spatial science, there are fewer potential applications of geographical expertise as generally understood, but this does not preclude engagement between professional geographers and the worlds they study. There has been growing interest, for example, in participatory geographies, action-orientated research involving engagement with, rather than just study of, individuals, groups, and communities (Pain, 2003); the research itself is collaborative and involves not just enhancing appreciation of situations but assisting campaigns for change. These have their roots in the anarchist writings of Kropotkin and Reclus (Springer, 2012), later developed by Bunge (1971) as 'geographical expeditions.' Whereas such work is emancipatory in its aims, its context is generally local, although Harvey links grassroots movements for change with the larger goal of replacing capitalism (Harvey, 2012).

More generally, there has been a substantial interest in 'critical human geographies,' the subject of a series of major international conferences focused on critical and emancipatory discussion aimed at radical explanation and change. These place as much emphasis on the 'ought' as the 'is,' on not only unmasking power in all its forms and the inequality it breeds but also emancipating people so that they are not just aware of how spaces and places are being manipulated but can also develop geographies of resistance (Pile and Keith, 1997; Blunt and Wills, 2000). Linked to this is work on the geographies of justice and ethics (Smith, 2000). Geography in such contexts is being applied in the interest of transformation, reflecting Harvey's earlier arguments that applications of spatial science may alleviate some superficial problems but not contribute toward the creation of a different, fairer world (Harvey, 2000).

Conclusion

Human geography is a large, diverse, expanding, and vibrant discipline characterized, like most others, by fragmentation and tensions – it is divided philosophically, methodologically, and politically. It has an established niche within the academic division of labor, with many productive interdisciplinary interactions: its core concerns – environment, place, space, scale – crystallized over a century ago remain its foundations, but its practices – what it studies, how and why – have changed markedly (as illustrated by the five editions of *The Dictionary of Human Geography*; Gregory et al., 2009). Buttimer (1993) has suggested that throughout their discipline's history, geographers have deployed four foundational metaphors (mosaic, machine, organism, and arena), with each more relied upon in some periods than others – though without the academic revolutions associated with Kuhn's (1970) paradigm model of the history of the natural sciences. Contemporary spatial science employs the mosaic metaphor (having largely abandoned the machine metaphor used in earlier decades to account for the mapped mosaics); contemporary social theory concentrates on organism and area – the spatial contexts (places, locales, milieux) implicated in the production of humanness while themselves being produced and reproduced by human action.

Abstract

Geopolitics is a term encompassing a diversity of thought and practice that extends far beyond the academy. From its initial preoccupation with imperialist struggles closely linked to the survival of states and empires, geopolitics continues to attract attention in the policy realm with the unfolding of great power rivalries and global hegemonic agendas. The infusion of 'critical' perspectives into the study of geopolitics has challenged the existence of objective scriptings of political space, highlighting geopolitics as a power-laden pursuit instead. As critical geopolitics diverge into 'newer' interests such as investigations of affect/emotions and assemblage thinking, there remains the need to be vigilant of the geostrategic knowledges that are invoked in the service of warfare and their multifarious impacts on society and its people.

Introduction

Geopolitics is a term that continues to attract a range of reactions including approval and opprobrium, although not always in equal measure. From its formal inception in the 1890s, the term 'geopolitics' has mushroomed to embrace a wide variety of thought and practice, and as a consequence a diverse range of stakeholders that extends far beyond the academy. While recognizing diversity is important, we can identify nonetheless a series of themes and motifs that continue to prevail. One area worth highlighting right at the start is a concern for how the physical environments of the earth shape the operationalization of power. In other words, geopolitical writers continue to be fascinated by the power of the earth, in the form of mountains, rivers, seas, deserts, and the like to shape political geographical relations. One contemporary example would be the Arctic region and the arguments that are raging about what continued sea ice thinning will do to the regional dynamics of this part of the world. The consensus of opinion, among the geopolitical community, seems to be that the Arctic is going to become more accessible and more exploitable. Where the community divides is whether this will encourage more consensual or conflict-based behavior.

The second area of interest is in state territory and state power (*see* State, Geography of). Ever since the earliest European commentators in the late nineteenth century embarked on explicitly geopolitical exchanges, interest loomed large in the role of populations, resources, and territorial advantage. Such an interest provoked further reflection either on how states/governments might better secure their national territories and/or resist other states who were operating in an international political world imagined to be uncooperative and even anarchical. Armed with ideas associated with social Darwinism, the state was frequently conceived as a living organism needing protection from predatory others eager to take advantage of additional territory and resources. Such a dystopian view of the world order played its part in ensuring that geopolitical ideas and practices were later to be condemned as intellectually poisonous, as critics claimed that the German Nazis and other fascist governments in Italy and Japan drew intellectual and practical inspiration from geopolitical doctrines.

The third theme worth stressing is alternative geopolitical ideas and practices. Geopolitics remains a contested enterprise. While it has long appealed to the powerful, there have always been counterprevailing tendencies (resistance, subversion, dissent and alternative imaginations, and practices) within the academy and beyond. Such struggles to resist dominant geopolitical imaginations find expression, therefore, in a diverse range of sites and spaces involving multiple agents such as anti-imperialists, governments in the global South, opposition movements, journalists, activists, and dissenters throughout the world. One example of someone who actively articulates a counter-geopolitical imagination is the long-serving president of Zimbabwe, Robert Mugabe. Since his election to political office in 1980, Mugabe has argued that Zimbabwe has to resist the dominant geopolitical machinations directed against his country by the former imperial power, the UK and other Western allies such as the United States and European states. As he claimed in 2002 at the Earth Summit in South Africa following criticism of his political rule and associated human rights abuses, "We have fought for our land, we have fought for our sovereignty, small as we are we have won our independence and we are prepared to shed our blood …. So, Blair keep your England, and let me keep my Zimbabwe." Mugabe might well think that he is practicing a form of critical geopolitics, one that highlights the discursive and material inequalities in contemporary global geopolitics alongside inherited imperial legacies.

Bearing the above in mind, this short article has two substantial sections. The first addresses some of the central tenets associated with classical geopolitics and the second section touches upon the literature associated with critical geopolitics. We conclude briefly with an assessment of the outstanding areas of research.

Classical Geopolitics

The earliest classical geopolitical writings were informed by imperial preoccupations and social Darwinist anxieties about the survival of states and empires. Writing in the latter part of the nineteenth century, the German writer Friedrich Ratzel

(1844–1904) expressed some of the dominant trends in classical geopolitics including racial and environmental determinism. Distinguishing between settled and nomadic communities, Ratzel argued that the settled Aryan races in particular were vulnerable to the marauding and thus hypermobile Ural–Altaic races. As a consequence of this perceived vulnerability, the Aryan races were the earliest to develop statelike structures designed to organize defense against mobile and, in all probability, threatening others. Ratzel contended that contemporary Germany should strive to secure additional land and resources so that it was better able to secure the survival of the nation-state in the face of Eastern races and their traditions of mobile existence. The term *Lebensraum* (living space) is particularly associated with the writings of Ratzel as a consequence of his interest in the interrelationship between environment, state, and culture.

While Ratzel's writings were infused with racial and environmental indices, the British writer Halford Mackinder (1861–1947) highlighted another aspect of classical geopolitics, namely a concern for grand strategy. Mackinder, a reader in geography at Oxford University and director of the London School of Economics, was primarily worried about Britain and the British Empire (Blouet, 1987; Kearns, 2009). Mindful of gathering imperial competition, Mackinder warned that traditional sea powers such as Britain were under threat from new land-based powers that might, with the help of new transport technologies such as the railway, be able to mobilize their populations and resources in a decisive manner. Intrigued by the historic significance of migrant empires such as the Mongols, Mackinder divined a future possibility based on new great powers (such as the latter day Soviet Union) using what he termed the 'heartland' to project power over the European continent. Vast quantities of coal, oil, gas, and other minerals, transported by railways, would quite literally empower those who controlled the heartland. In his famous epithet, Mackinder warned his readers that "who rules East Europe commands the Heartland. Who rules the Heartland commands the World-Island. Who rules the World-Island commands the World" (Mackinder, 1919).

These brief sketches of two classical geopolitical writers highlight the dominant strands of classical geopolitics – on the one hand, social Darwinism and environmental determinism and, on the other hand, imperial rivalries and great-power projection. In the case of the former, the earliest geopolitical writers were overwhelmingly informed by racial and environmental determinism. Most contributors were eager to warn their political masters and the wider public about the challenges facing their societies from competitor races and states, both past and present. Geopolitics was, and for many authors still is, the study of statecraft and the divination of patterns of global politics. If geopolitics has an intellectual value, it lies in a capacity to uncover the challenges facing the state and empire, and a willingness to use force if necessary to protect vital interests.

The controversial reputation inherited by geopolitics owes much to a particular moment in the interwar period when the subject became linked with more widespread fascist and authoritarian strands of thought in Germany, Italy, and Japan. With its focus on territorial and resource-related factors, geopolitical thought attracted the interest of writers such as the German military officer and professor of geography at the University of Munich, Karl Haushofer. In 1924, he founded the *Zeitschrift fur Geopolitik*, a journal that was to explore how Germany might recover from the humiliating loss of the World War I and the sorts of geographical strategies need to stimulate revival. Geopolitics, according to Haushofer, should be an accomplice of the state and encourage an expansion of Germany, possibly leading to leadership of the Euro-Asian landmass in alliance with Russia and Japan. Combining the global strategizing of Mackinder with social Darwinist insights including the state as a living organism, a geopolitical perspective armed with maps and statistics was believed to be an indispensible part of the state and its intellectual armoury. As with Fascist Italy, this academic interest was supplemented by popularizing trends with a new generation of school children being instructed on the spatial extent of a Greater Germany and Italy (Atkinson, 1995). Under this worldview, the state needed to expand into new territory and acquire new resources in order to restore itself to health.

For American-based geographers, including refugees from Nazi Germany, geopolitics was at best a 'pseudoscience' and at worst a 'Nazi science.' Either way it stood accused of acting as a willing accomplice to the worst excesses of territorial domination and spatial expansionism. With the onset of the World War II, this jaundiced view of geopolitics hardened. American and European geographers such as Isaiah Bowman, Derwent Whittlesey, George Kiss, and Jean Gottmann warned that geographers should steer clear of the subject matter and concentrate their energies on developing a scientific political geography (as noted in Dodds, 2010). While this alleged association between Hitler and geopolitical scheming was perhaps not as straightforward as implied by the critics, it did prevent the Roosevelt administration from commissioning a special study of German geopolitics in order to consider its resonance and influence among Hitler's cabal. Senior geographers such as Karl Haushofer, while hardly bystanders, did not share Hitler's preoccupation with race and hatred of Jewry. They were, however, eager to put forward proposals for Germany to restore its proper place in the world and supportive of the idea that the country needed to expand into new territories. Popular magazines such as *Reader's Digest* played their part in warning international readers that the Nazis created a shadowy Institute of Geopolitics in Munich and that there were a '1000 scientists behind Hitler' using charts, maps, statistics, and plans to facilitate further expansion and conquest.

Accused of being an accomplice to Nazism, geopolitics became an academic field best avoided for many geographers in the USA and Europe. The end result was twofold. First, there was a general reluctance to use the term 'geopolitics' explicitly and, second, attention turned to seeking a new social scientific language based on modeling and testing that would replace any notion that the state was a living organism. For much of the post-1945 period, explicit references to geopolitics were limited in number and scope even if well-known figures such as George Kennan were to talk and write about continental powers, the Euro-Asian landmass and resource potential of regions. As Richard Hartshorne reminded his readers: "We may have produced no atom bombs in political geography, but the field

is nonetheless strewn with dynamite – it is no place for sophomores to play with matches" (cited in Kearns, 2011: 614).

Henry Kissinger is famously credited with making geopolitics respectable again in US policy-making and academic circles (1979). In the early 1970s, geopolitics became a short hand for highlighting great power rivalries and associated regional dimensions, especially in the Middle East and Southeast Asia. As National Security Advisor and Secretary of State in the Nixon and Ford administrations, Kissinger was well placed to survey the global political scene and ruminate on the geopolitical consequences and implications, more often than not involving military force and assertion. As Leslie Hepple reminds us, Kissinger's geopolitics was often fuzzy and vague, even if it had as its basis an interest in superpower rivalries and the global stage (1986). Other contemporaries such as President Carter's National Security Advisor, Zbigniew Brzezinski, also used geopolitical language to promote his view that control of the 'heartland' (a point of view articulated by Mackinder some 70 years earlier), was critical to the future patterns of global politics. As Brzezinski noted, "whoever controls Eurasia dominates the globe. If the Soviet Union captures the peripheries of this landmass … it would not only win control of vast human, economic and military resources but also gain access to the geostrategic approaches to the Western Hemisphere – the Atlantic and Pacific" (1986: 22). For the USA to retain its global prominence, it would need, by force if necessary, to ensure that vital resource supplies and territorial access were secure. Moreover, as US covert support for anti-Soviet forces in Afghanistan in the 1980s suggests, it would require investment in opportunities that might disrupt any attempt by the Soviet Union to project further its domination of the Eurasian landmass.

The net result of this resurrection of interest in geopolitics in the 1970s was to remind us why geopolitics continues to inspire a great deal of interest and, as noted earlier, distrust. If there was a revival – acknowledging the long-established interest in the field in the former Soviet Union and Latin America, where it has been closely tied to forms of military geography (*see* Military Geography), then it was based on a predilection for global perspectives; skepticism about international diplomacy and law; an understanding of power relations as a zero-sum game; a belief in the importance of resources such as oil, gas, coal, and minerals; a stark contrast between land- and sea-based powers; and finally a willingness to urge intervention (or sometimes nonintervention) where national security interests were at stake (for a critique, see Kearns, 2011).

Critical Geopolitics

The renewed interest in geopolitics in the international political/policy arena garnered the attention of many scholars, not least Les Hepple who published an influential article in 1986 titled, "The Revival of Geopolitics." In his paper, Les Hepple was not only concerned with the "'social life' of geopolitical ideas: how they 'travel' between places, how they were adapted, contextualised and repoliticised through specific tactical deployments or denouncements" (Megoran, 2008: 403). More importantly, he argued that this exercise of tracing the adaptations and mutations of geopolitical discourses will form the necessary premise for challenging dangerously misleading geopolitical doctrines and policies in discrete contexts. Les Hepple's provocative call for deconstructive geopolitical engagements through responsible scholarship has characterized the field of critical geopolitics, conceived of by O'Tuathail (1996: 256) as one of the "cultures of resistance to Geography as imperial truth, state-capitalized knowledge and military weapon." Indeed as Atkinson (2001: 426) has noted, Hepple's insights foreshadowed concerns that would later occupy critical geopoliticians and presaged the inquiries of critical geopolitics, conveying "a sense of the arbitrary and diverse use of the label, and an impression of the plural contexts wherein geopolitics surfaced." As a broad set of writings that first emerged in the early 1990s, critical geopolitics came under the radar of the geographical discipline through the seminal works of O'Tuathail and Agnew (1992), O'Tuathail (1996) and Dalby (1990, 1991). These pioneering research quickly proliferated into an extensive array of publications that helped to shape the intellectual boundaries and trajectories of the now established field of critical geopolitics. Influenced by post-structuralist philosophies particularly emanating from Michel Foucault and Jacques Derrida's works, the initial impetus of critical geopolitics was to generate new ways of thinking about how global political space is being constructed, represented, and practiced. In Dalby's (2010: 281) words, there were "concerns about disrupting the hegemonic practices of statecraft, challenging the taken for granted specifications of the world in various mappings by elites and academics." What this signifies is that there is a more explicit focus on the dual issues of agency and power: who is sculpting/representing the terrains of geopolitics and for what purposes and agendas. In doing so, there can be more nuanced expositions of the deployment of geopolitical discourses in the service of exclusionary and violent state power.

Indeed, there have been ongoing efforts to recover "textuality within practices which are represented as objective or practical, as 'beyond the text'" (O'Tuathail in Jones and Sage, 2010: 316). In such a conception, geopolitics is not something 'out there' that can be objectively observed and analyzed; rather it is actively played out through the complex web of language and (con)text. As such, geopolitical discourse in global politics is understood to be the outcome of perpetual 'geo-graphing': the production and dissemination of strategic maps and texts (Dodds and Sidaway, 1994). Aligning to this position, critical geopolitical writers have demonstrated that the ability of political elites to depict and represent places in certain ways should be an important component of investigating international politics. This line of inquiry emerged primarily as a challenge to American military power during the Cold War era: critical geopolitics were keen to expose how geographical knowledges were invoked to bequeath certain characteristics to specific places so as to make them amenable to US's intercession and mode of governance (e.g., the Antarctica) (Dodds, 1997). With the end of the Cold War, critical geopolitics began investigating the shifting of global security from the dangers posed by Communism/the Soviet Union to matters of development and insecurity at the fringes of global political economy. New

insecurities came in the form of weak/failed states and wild zones, as portrayed by many policy-making bureaucracies (O'Tuathail and Luke, 1994). These caricatures continue to find resonance in a world dominated by conspiracies of terror in the aftermath of the 11 September 2001 attacks on New York and Washington. Mapping dangerous places and formulating effective interventions once again captured the imaginations of military cartographers and geostrategists (Barnett, 2004; Kaplan, 2009). Critical geopolitics has proved particularly instructive in reminding us that the planet's transformation into a battlefield as a consequence of the 'global war on terror' cannot be divorced from the ways in which threats are imagined and spatialized so as to legitimate (America's) political power and hegemony (Gregory, 2004).

While critical geopolitics involves fundamentally unpacking the tropes and epistemologies of dominant geographs and scriptings of political space, its proponents are quick to note that there are multiple pathways to attain such a goal. Beyond state-centric readings of world politics, critical geopoliticans are keen to illuminate the messy and mundane practices that constitute the modern interstate system. In other words, geopolitics is inescapably plural and this has opened up the range of sites/texts and practices where 'geopolitics' is seen to take place (O'Tuathail in Jones and Sage, 2010). Examples include works on anti-geopolitics that study nonstate actors such as social movements and transnational organizations (Routledge, 1996, 2002); and on popular geopolitical representations contained within magazines (Sharp, 2000), cartoons (Dodds, 2007), films (Dodds, 2006; Dalby, 2008), Internet platforms (Mamadouh, 2003; Woon, 2011a), and digital video games (Power, 2007) along with a burgeoning focus on geopolitics, visuality, and visual culture (Hughes, 2007; McDonald et al., 2010). Such a diversification of geopolitics has also led to heightened interest in different traditions and historical contexts in which geopolitics has been written and interpreted. Indeed, following Hepple's initial exposition of the Latin American and Rumanian strands of geopolitical thought, critical geopolitics have since delved into understanding a growing range of formal geopolitical traditions (Dodds and Atkinson, 2000). From Italy (Atkinson, 1995) to France (Fall, 2007) to Spain and Portugal (Sidaway, 2000; Sidaway and Power, 2005), reflections abound on the historicity of geopolitics, drawing upon the debates over writing more contextual accounts of the histories of geographical knowledge (Livingstone, 1992).

Despite its vibrant development over time, critical geopolitics as a field of study has been criticized for being overly normative and not living up to its political potential. Dalby (1996) notes that the 'critical' in critical geopolitics usually refers to the problematization of discourse rather than the presence of a worked out, alternative political project (see also Dowler and Sharp, 2001). Hyndman (in Jones and Sage, 2010: 317) likewise argues that "in its quest to destabilize the normative, critical geopolitics rarely engages in transformative and embodied ways of seeing and knowing." Kelly (2006: 43) on the other hand, lambastes critical geopolitics for offering "neither a clear characterization of a better society nor a specific road map for attaining such an improvement." In lieu of such critiques, there has been the rise of numerous intellectual initiatives that seek to steer the subdiscipline into new directions for critical engagements. For instance, Jennifer Hyndman (2004, 2010) has, for some time now, made the case for a feminist geopolitics and an embodied politics of shared fate so as to realize the possibility of nonviolence in facilitating interactions in the global arena. Similarly, Mercille (2008) proposes a 'radical geopolitics' to reinvigorate the political spirit of geopolitics, suggesting that political economy might be the way forward in terms of identifying some of the structural underlying practical geopolitical decision-making and global inequalities, helping us to explore the 'why' as well as 'how' of political/economic policy decisions. Additionally, Koopman (2011) evokes the term 'alter-geopolitics' to foreground the connections between critique and political activism. Specifically, she casts attention on the grassroots movements that build international relations of solidarity for active peacemaking, arguing that academics might simultaneously take on the activist persona to translate their geopolitical theories into positive, material outcomes.

Although diverging in their exact focus, these aforementioned geopolitical agendas are united in their insistence to ground geopolitics in particular places. This links to Thrift's oft-cited claim that critical geopolitics' apparent mesmerized attention to texts and images has led it to neglect the 'little things.' Thrift calls for more sensitive inquiry into the workings of geopower, by attending to objects and issues related to embodiment. This simultaneously entails critical geopolitics to expand its methodological repertoire (beyond discourse analysis) to experiment with 'traditional' modes of doing geography: fieldwork, ethnography, and interviews (Megoran, 2006; O'Tuathail, 1998; Woon, 2013). These various dimensions and challenges have been undertaken by a plethora of work in recent years. While it is impossible for us to cover such research in their entirety, we will zoom in on what we think are two most exciting developments in critical geopolitics.

First, matters of percept, affect, and emotion, as well as the most ordinary ('precognitive') forms of sociality have entered into the research domain of critical geopolitics (Power and Campbell, 2010). A few examples will suffice to illustrate this point: O'Tuathail's (2003) work on how affect is implicated in the US's invasion of Iraq, Carter and McCormack's study on film and the affective logic of intervention and Pain's (2009, 2010) investigations of the emotional geographies of fear that underpin the 'war on terror.' Most recently, these textual themes have been complemented by looking at their localized politics of reception and interpretation. The current discussion of audience reception, fandom and how readers and viewers consume movies and other cultural products extends analysis of critical geopolitics in another useful direction (Dodds, 2006; Dittmer and Dodds, 2008). And so do research focusing on the ways in which the emotive infrastructures of warfare are responded to by affected communities on the ground (some culminating in hopeful outcomes whereby emotions are stimulating actions and shaping the practices and progress of radical praxis at different geographical scales) (Pain and Smith, 2008; Woon, 2011b).

Second, the infusion of assemblage thinking into critical geopolitics has also offered stimulating prospects for the field. According to Anderson et al. (2012: 173), the concept of assemblage provides something significant and unique

insofar as it allows analyses to "attend to how often disparate activities become entangled with one another, but nonetheless have potential agency beyond those interactions which may later become parts in other assemblages." Adopting such a relational approach, Anderson (2010), for example, illuminates how a form of anticipatory actions such as preemption in US counterterrorism policy is constituted through the redeployment of elements from other ways of acting over futures as well as the intensification of dormant tendencies in linked areas of public policy. Preemption emerges as a coherent and distinct way of reordering space, even as it is always involved in a series of partial connections with other ways of acting over threats and hazards. Alternatively, Muller (2012) casts scrutiny on organizations as one underresearched actor in critical geopolitics. Conceptualizing organizations as assemblages that are constituted through complex social material networks, Muller exhorts for organizations to be given more attention in the subdiscipline due to their complicity in the continuous processes of geopolitical ordering. Hence, through these writings, we can see that assemblage offers a sustained account of the multiple ways in which geopolitical orders endure across differences and amid transformations, in addition to a sensitivity to how such orders are changed and reworked.

Concluding Remarks

We are not trying to posit a strict dichotomy between classical and critical geopolitics nor are we suggesting a linear progression from the former to the latter. As O'Tuathail (in Jones and Sage, 2010: 316) reminds us, critical geopolitics is not simply a more advanced or superior version of its classical variant. Rather "in exposing geopolitics as a convenient fiction, critical geopolitics reveals itself as a similarly convenient fiction of opposition. It is merely the starting point for a different form of geopolitics …." After all, it must be remembered that the fundamental impetus of critical geopolitics is precisely to question the power/knowledge imbued in classical geopolitical discourses. In other words, the development of critical geopolitics cannot be adequately analyzed or fully appreciated without reference to its classical counterpart.

Indeed, the continued need for critical geopolitics to deconstruct and expose how geostrategic knowledges are used to legitimate warfare has been demonstrated by a number of scholars. By underscoring the geographical tropes of warfare embedded within Robert Kaplan's (2009) work, Dalby (2010), for instance, concurs with Fraser MacDonald's (in Jones and Sage) assessment that the persistence of classical geopolitical reasoning makes sustained critique necessary. Both MacDonald and Dalby are wary that critical geopolitics' forays into a host of other research avenues (the 'little things' such as affect/emotions, lived experiences of people, etc.) will dilute its original purpose concerning the writing of global political space (i.e., the 'big things'). But if we accept O'Tuathail's (in Jones and Sage, 2010: 316) claim that critical geopolitics is "no more than a general gathering place for various critiques of the multiple geopolitical discourses and practices that characterize modernity," the eclecticism of the field can only be seen as a stimulating and necessary intellectual and political project to engage with some of the most pressing issues of our times (terror, diseases, migration, human rights, and environmental risk) as part of a wider set of critical approaches to political geography (*see* Political Geography). What perhaps needs to be further pursued then, are critical studies on the ways in which the 'big' and 'little' things of geopolitics are intimately connected. This necessitates a multiscalar approach to understanding geopolitics and its multifarious impacts and relevance on society and its people.

Geospatial Applications in Archaeology

Devin A White, Oak Ridge National Laboratory, Oak Ridge, TN, USA
Katie A Corcoran, University of Tennessee, Knoxville, TN, USA

Abstract

Archaeology is an inherently spatial discipline and archaeologists have long created and used maps to help them make sense of the past. Among field scientists, archaeologists were also some of the earliest adopters of geospatial technology like geographic information systems, spectral imaging, and laser scanning, all of which have enabled significant discoveries in recent years. As those technologies have become more widespread and sophisticated, so has their use within the field. This article provides an overview of core concepts, technologies, and analytical methods.

Introduction

Archaeology is an inherently spatial discipline. Beginning with excavation, space and time are controlled to the maximum extent possible. Artifacts and features are gradually exposed and mapped through careful horizontal excavation. Site formation processes are gradually understood and mapped through careful examination of stratigraphic profiles. Dates are assigned to everything that can be dated. This attention to spatiotemporal detail allows archaeologists to reconstruct past events and to explain what happened in a particular place at a particular time. The same approach holds at coarser scales, where the locations of households, villages, cultural areas, language groups, exchange systems, migration routes, chiefdoms, and states are mapped in space and time in an attempt to understand broader patterns of human behavior. In this context, the term 'geospatial applications' can be interpreted to mean putting the well-established cartographic and analytic methods used by archaeologists in a more exact locational context, where maps are produced with ever-increasing accuracy and coordinates are tied to real-world projection systems like Universal Transverse Mercator to facilitate interoperability and collaborative research. Doing so, however, misses the point. While archaeologists have taken full advantage of improvements in technology to make better maps, they have also started to leverage more sophisticated forms of spatiotemporal data collection and analysis to generate more meaningful insights. This article will discuss both aspects of geospatial applications in the discipline, beginning with advances in digital cartography, moving to prominent data collection platforms, and concluding with common analytical activities.

Geographic Information Systems

The geographic information system (GIS) concept has transformed and democratized the cartographic aspects of archaeology. At its most basic level, a GIS is a digital framework that allows a researcher to assemble layers of spatially referenced information into a single package that can then be modified as needed to easily produce professional-quality maps. The two most common types of layers are raster (a regularly spaced grid of values, like an image) and vector (points, lines, and polygons). The layers can come from almost anywhere, including satellite images, digital elevation models (DEMs), virtual reconstructions, data collected via GPS in the field, and scanned/digitized maps pulled from older reports or historical sources, but the unifying core concept is that they can all exist within a common real-world coordinate space. This framework gives archaeologists unprecedented control over what kind of stories their maps tell and the flexibility to play with multiple display and layer ordering concepts in a relatively risk-free and low-cost way. Until fairly recently, the only robust GIS software package available to archaeologists was ArcGIS, developed by ESRI. While it is still considered to be the gold standard, significant advances in the open source software domain – in direct response to the relatively high cost of an ArcGIS license – have led to the emergence of two free competitors: GRASS and QGIS. For basic cartographic tasks, all three applications enjoy widespread use within the discipline.

GIS is much more than digital cartography, though. Once information layers are brought into a common space, they can be visually altered, manipulated through algorithms, and/or mathematically combined to produce new information and, ultimately, new insights. This is one of the biggest growth areas for archaeological analysis, given the ubiquity of geospatial data in today's world and the wide variety of other disciplines working on similar or at least somewhat related problems.

GIS has permeated archaeology, but it is largely up to the individual researcher to learn how to use it, leading to the development of bad habits, fundamental knowledge gaps, and a lack of standards and best practices. Some academic archaeology programs, especially outside of the United States, offer training courses in the basics of GIS; a very small number have GIS degree emphasis or certificate options. Also, there is currently no standard reference volume for how GIS can and should be used within archaeology. This situation must improve if the discipline is to fully embrace the technology and all that it has to offer.

Popular Online Geospatial Data Visualization Tools

The world is currently experiencing a geospatial data revolution, fed in large part by the activities of large technology companies like Google, which develops and freely distributes

two widely used data visualization platforms: Google Maps and Google Earth. Both are in essence simplified GIS software packages, which, at their most basic levels, allow you to view street maps and satellite imagery for almost any point on the earth's surface from the comfort of your desk in two or three dimensions, respectively. For the public in general and archaeologists in particular, this is usually their first exposure to remotely sensed data like satellite images and other geospatial products like hydrology maps and DEMs. The currency and quality of the maps and imagery hosted by Google varies widely, but for the most part the company endeavors to provide a good experience in most populated places as well as remote areas that are well-known by the general public (e.g., Grand Canyon). All other remote areas receive updates far less often. Due to the fact that both platforms can be used for free, many professional and avocational archaeologists have spent large amounts of time exploring hosted imagery, looking for previously unknown sites or assessing change at known ones. These explorations have led to amazing and dubious discoveries, but both outcomes reinforce the fact that fieldwork must be done to verify anything found in imagery collected from a significant distance.

Because of how Google Maps and Google Earth are developed and distributed, it is difficult, but not impossible, to do more than view hosted maps and imagery. Users can create their own maps for viewing in Google Maps from geospatial content hosted elsewhere on the Internet, but geospatial analysis is not currently supported. Google Earth does allow the importing of custom raster and vector datasets created using third party software and relying upon a web standard known as Keyhole Markup Language. It also allows users to import three-dimensional models built using free software like Google SketchUp, so reconstructions of archaeological sites can be placed in their approximate locations on the Earth's surface to aid in contextual analysis. With that said, importing large datasets of any type tends to drastically slow down the application. When this happens, it is time to switch to a more robust solution.

While the names and capabilities of online geospatial tools will likely change in the coming years, the trend of working with large amounts of data remotely, through a lightweight application like a web browser, is here to stay. Most desktop computing tasks will be transferred into this domain, which will allow researchers to ask larger and more complex questions without having to invest in specialized hardware and software.

Prominent Geospatial Data Collection Platforms

This section will highlight the two most prominent types of geospatial data collection platforms in use today: spectral imaging and laser scanning. These platforms are complementary, with the former recording how electromagnetic energy either reflects off of or is emitted by objects and the latter using reflected electromagnetic energy to record the precise shape of the objects and their locations. Either one can be used separately, but leveraging both can produce much better results. For the purpose of brevity, the following discussion is primarily focused on how the platforms are deployed via aircraft (spectral and laser) and satellite (spectral), but the same general principles apply to data collected on the ground at much finer spatial resolutions.

Spectral imaging is a dynamic technology applied to archaeological site detection, site characterization, and predictive modeling. The imagery available through applications like Google Maps and Google Earth is produced by spectral systems, but the user is only seeing a small fraction of the data collected (just what our eyes can see) and is not able to perform quantitative analysis. While often used to supplement other remotely sensed data or a GIS, spectral imagery is usually delivered as a stack of images, with each one representing a different portion of the electromagnetic spectrum. These 'slices' can be analyzed individually or as a whole, supporting manipulation to derive secondary products for additional analysis, classify objects in an image, build a reference library for use with similar imagery, or simply emphasize certain visual features of a landscape. Like other remote sensing technologies, spectrometry is attractive to archaeologists due to the large amount of land area that can be quickly imaged. Further, spectral imagery can reveal qualities of archaeological sites and features, or their proxy effects on the surrounding environment, that are not visible to the naked eye. For example, buried archaeological materials might affect how plants grow on the surface, which can be detected by sensors as differences in how certain wavelengths of light are absorbed or reflected by those plants when compared to their neighbors (Parcak, 2009). Near-infrared light, which cannot be seen by humans, is among the most widely examined. It is important to note that spectral imaging is considered to be a passive remote sensing technology, in that the sensor opportunistically collects the energy that reaches it. In contrast, active systems send out their own energy pulses and wait for them to return.

Introduced to archaeology a bit earlier than other remote sensing technologies, spectral imaging became popular in the mid- to late-1970s, becoming what is now one of the most common modern remote sensing approaches in the discipline. Most of the examples of spectral imagery use in archaeology are of work done in Western Europe (Campana, 2002; Ciminale et al., 2009), the Americas (Custer et al., 1986; Masini et al., 2009), and Western Asia. By comparison, surprisingly little work using spectral imagery has been performed in Africa (Clark et al., 1998; Parcak, 2009).

The availability of no- or low-cost satellite spectral imagery has resulted in the increase of its use within many disciplines. Archaeologists are using the imagery in creative ways, often optimizing it by correlating spectral responses with other data sources like Synthetic Aperture Radar (Vining and Wiseman, 2006), satellite photography (Scardozzi, 2008), GIS (Sarris et al., 1996; Vaughn and Crawford, 2009), and even other spectral sensors with differing spatial and spectral resolutions (Leucci et al., 2002; Sarris et al., 2013). Spectral data are often leveraged to create proxy indications of archaeological site presence and distribution, to varying degrees of success. The most well-known proxies involve the cross-examination of different spectral bands for detailed analyses of vegetation presence, plant species identification, soil and plant moisture content, and overall vegetation health. Of the well-known proxies, the most used is

Normalized Difference Vegetation Index (cf Masini et al., 2009).

Beyond data fusion or predictive modeling, spectral imagery can be used to manually or automatically classify objects in an image. Buildings, roads, vegetation, and water are commonly classified early on so a researcher can focus on spectral signatures within the image that are anomalous or patterned, and are perhaps of significant interest to an archaeological investigation. Similarly, the spectral signatures of known archaeological sites in an image can be defined by a user and leveraged to locate similar signatures in the same image, or a different image – areas which may also contain archaeological sites. These methods are common practice in spectral imagery analysis. If done carefully, spectral reference libraries can be established using these observations, ones that can be used in related contexts as a way to save time and maintain consistency between analyses and researchers.

Laser scanning, generally referred to as light detection and ranging (LIDAR), is an active three-dimensional data collection method that has been used by archaeologists for identifying or confirming the spatial extents of sites, for visualizing known and unknown features on the ground surface, and in combination with other data to develop predictive models of archaeological site location. In brief, a single laser beam or collection of beams is directed toward the ground and the time it takes for the beam(s) to return to the sensor, in combination with data about the sensor's current position and orientation, is used to calculate precise coordinates for each return with very small error estimates. Those returns are stored as points, collectively referred to as a point cloud, and are then subjected to one or more processing techniques in order to highlight features of archaeological interest. In many cases, the spatial complexity of the point cloud is reduced to that of a DEM (height measurements on a regularly spaced grid) for software compatibility and ease of use.

The mid-2000s brought about an increased popularity of laser scanning technologies in archaeological investigation. The use of LIDAR in archaeology has grown rapidly and case studies have been published for work done throughout the world, with a clear emphasis on prehistoric sites in the UK and North America (Chase et al., 2011; Dorshow, 2012). Historically, archaeologists have spent their limited time and project funds investigating features discovered through ground-based surveys, native accounts, and/or aerial photography – all which rely on the ability to identify and record areas of interest without much visual assistance. Since the introduction of LIDAR to archaeology, it is becoming increasingly common to scan landscapes in search of subtle artificial features that are not otherwise obvious, then follow up with fieldwork to confirm their significance. In several recent studies, the use of LIDAR has greatly expanded our understanding of the size and complexity of even extremely well-known sites (Chase et al., 2011; Evans et al., 2013; Fisher et al., 2011).

Two scales of LIDAR are common in archaeology: airborne and terrestrial. Airborne platforms are flown overhead, while terrestrial scans are generally collected from a stationary tripod-mounted platform. Airborne LIDAR has traditionally been preferred, but terrestrial LIDAR is becoming increasingly popular due to its relatively low acquisition cost, ease of use, and ability to capture a significant amount of detail over very small areas (e.g., individual sites and features). This historical trend is demonstrated by an overwhelming number of case studies using airborne LIDAR data in archaeology as compared to the handful of terrestrial LIDAR surveys, but the balance is expected to shift in coming years. It is also important to note that the two scales are not mutually exclusive. Some archaeological projects call for analysis at the landscape and site levels.

LIDAR scans generate point clouds that must be filtered to remove obstructive objects like vegetation, before subtle archaeological features become apparent (White, 2013). Many different strategies exist for point cloud filtering, and there are techniques designed for airborne and terrestrial point clouds – with a separation of techniques between data types firmly maintained in the literature by researchers (i.e., airborne filtering techniques are always applied to airborne LIDAR point clouds, and the same rule is followed for terrestrial LIDAR) (Zhang and Whitman, 2005). This is due to distinct geometric differences between the two types of LIDAR data that stem from different sensor orientations relative to the ground or object. There is a relative lack of research on terrestrial LIDAR point cloud processing and analysis within the discipline, likely because it is a newer approach to archaeological investigation. As more processing techniques are developed and become popular, there may be a proportional increase in the use of terrestrial LIDAR by archaeologists.

Since many archaeologists prefer to visually browse their LIDAR data in search of potential archaeological features, effective visualization methods are critical. For example, after filtering out all nonground points, 'bare earth' DEMs can be generated and displayed in different ways to emphasize features on the surface. It should be noted that there is no one correct way to produce a bare earth DEM and none of the currently available methods are optimized for archaeological research. Each one requires experimentation with available software settings and may not be appropriate in all environmental contexts. Most archaeologists prefer the shaded relief visualization method (Horn, 1981), which simulates the projection of light from a single point onto the Earth's surface, simulating sunlit terrain. While shading in this way is by far the most popular visualization technique in published case studies, it is not without problems. Two issues in particular are (1) the 'shaded' areas often contain features that are easily overlooked because they are not directly illuminated and (2) linear features that are oriented parallel to the direction of sunlight are mostly illuminated, resulting in a partial or complete loss of visual detail (Zaksek et al., 2011). This is problematic for the archaeologist whose goal is to emphasize subtle features that may require further investigation. There are recent developments in DEM visualization that simulate diffuse rather than direct light, such as Sky-View Factor (Zaksek et al., 2011), that have improved the way LIDAR data are viewed. Diffuse lighting techniques are expected to gain traction in the archaeological community as an intermediate step to more advanced analyses that involve direct use of the filtered or unfiltered point cloud.

Common Analytical Activities

As mentioned above, archaeologists have begun to move far beyond mapmaking and simple visual analysis of geospatial

data. This last section highlights some of the most common analytical activities undertaken by researchers, albeit at a very high level due to space restrictions.

Spatial Analysis

The topic of spatial analysis in archaeology covers a lot of territory, but at its most basic level, geospatial data are supplied to one or more algorithms that (1) take sparse observations and attempt to fill in the gaps, (2) highlight spatial patterns that are not readily visible to the naked eye through the use of statistics and applied mathematics, or (3) reduce complexity so that the data become more digestible.

With respect to filling in the gaps, generally referred to as interpolation, there are several standard approaches, all of which operate under the assumption that you are starting with point observations and desire to create a continuous surface from them that speaks of trends over a landscape (**Figure 1**). The first, nearest neighbor, moves outward from each supplied point and fills in gaps based on the value of the nearest original point to the current location. Sometimes a decay model is applied during the search process to lessen the influence of known points as distance increases. The second, inverse distance weighting, starts with the use of an exponential decay model, but then either limits the number of points to consider or their distance from the current location during interpolation. The user's choice of how to limit the search will impact the final result. The third, natural neighbor, is the most complex. It begins by connecting all of the known points to one another through a series of nonoverlapping triangles, referred to as Delaunay Triangulation, then uses those triangles to create a set of nonoverlapping complex polygons that represent the neighborhood of influence for each known point. Gaps are filled in by weighing the influence of each neighborhood around a location and its distance from their centers. It is important to note that no one approach is better than another, but the researcher should be very clear in indicating which one they use, and why, when communicating analytical results and their significance.

Trying to discover hidden spatial patterns is another popular research activity. The most common approach is spatial autocorrelation, which is based on the principle that things closer together in space tend to be more like each other than things that are far apart. At its heart is a spatially-aware regression technique that attempts to highlight data patterns that are spatially dependent, which is of great use to archaeologists looking for similarities and differences between entities, and how those might change over time, at multiple scales of analysis. This kind of analysis can be done with both vector and raster data. Another area of emerging interest is spatial network analysis. Social network analysis has been around in the social sciences for decades (Borgatti et al., 2009), but the spatial form of this analytic technique is fairly new and of particular interest to archaeologists who want to examine synchronic and/or diachronic interconnectedness between communities. This can be done by building temporal graphs that connect communities through the one- or two-way exchange of particular resources, languages, and/or iconography, for example. Subjecting these graphs to algorithms that factor in not only the locations of those communities and time but also the strengths of connections and how the change can make the nature of the relationships between those communities much more apparent (Mills et al., 2013).

Finally, in terms of data complexity reduction, it is worth briefly mentioning a technique known as principal component analysis (PCA). Instead of indicating the degree of correlation between data that are spatially near one another, PCA removes the correlation in an attempt to highlight true differences and suggest which aspects of the complex data are the biggest drivers of those differences. This technique, in an aspatial form, is commonly used in artifact sourcing studies (e.g., X-ray fluorescence (XRF) and neuron activation analysis (NAA)) to

Figure 1 An example of interpolation, where the empty space surrounding individual data points (left) is filled in using the closest known values (right) to form a continuous surface. Colors are coded by data values, which appear next to each point.

determine which elements do the best job of discriminating source groups.

Terrain Analysis

Like spatial analysis, terrain analysis is an expansive subject that cannot be covered in detail here. There are four common analytical approaches that are used to aid in archaeological research, with each one focused on a different aspect of how physical terrain influences human behavior and interaction. For the sake of simplicity, all approaches discussed below relate to the analysis of DEMs. They can be extended to point clouds, but currently available GIS software does not handle that scenario well. Instead, point clouds are reduced in complexity to DEMs and fed into existing algorithms.

The first, morphological analysis, tends to be used to create inputs for the other three, and to aid in predictive modeling, but can also stand on its own. This type of analysis includes slope and aspect derivation, surface roughness derivation, surface type derivation (e.g., valley, ridge, plain), and the generation of both shaded relief maps and related products based on diffuse light.

The second, viewshed analysis, is concerned with how much of the landscape can be seen from a user-selected location on that landscape. It uses line of sight to paint regions of a DEM that are visible and those that are not. This technique is particularly useful when trying to determine which, if any, archaeological sites are visible to one another in a region, if a particular site is in a defensible location, or if any sacred landscape features are visible from a given site (or vice versa). In recent years, it has even been used to help delineate archaeological heritage protection zones where the viewshed is an integral part of the experience and should not be cluttered with signs of modern life (Davis et al., 2013).

The third, least cost analysis, deals with how people can move efficiently across the physical landscape. There are several variations to this type of analysis, depending on the interests of the researcher. The simplest one is proximity analysis, which generates a raster based on the input of a vector feature like a river network. Each cell in the raster indicates how far it is from the nearest part of the feature. Proximity rasters are often used as inputs to predictive models. A more complex approach is to pick a single spot and calculate the minimum cost, usually based on an easily quantifiable metric like distance traveled or time expended, from that location to every other location on the landscape, as well as the routes required to reach them. The most efficient route to each location may not necessarily be a straight line and those routes can be reconstructed by picking a location and tracing the decisions that led to reaching that spot in reverse, using an intermediate product known as the backlink, which most users of GIS software never see. What they do see is the route itself, delivered as either a vector line or a raster with only a small number of cells highlighted that indicates the route. This kind of analysis can be done with many locations, not just one, in order to get a more complete understanding of how people can move across a landscape. Knowing the most efficient ways to move between locations, and how they may or may not line up with known travel routes, is extremely useful information to archaeologists interested in patterns of movement related to exchange, migration, and warfare, just to name a few topics.

The fourth, hydrological analysis, can in some ways be considered a variant of least cost analysis. Morphological inputs derived from DEMs are used to determine the most likely routes water would take from the highest points on a landscape to the lowest. This kind of analysis can be used to determine watershed boundaries and extract potential stream and river networks, with associated flow rates. Knowing where water could be, especially on landscapes with only intermittent water flow through time, is integral to understanding decisions on matters like site placement and the construction of irrigation systems.

Chained Analysis

It is important to note that the analytical methods mentioned above rarely exist in a vacuum. Results from one are often fed into another, and then those results are passed into a third, and so on, until a final product is generated. This is generally referred to as chained analysis, or model building, and all of the currently available GIS software packages allow you to do it, usually through a drag-and-drop visual interface. The outputs of one process become the inputs to another, with the end result often being something like a predictive map of archaeological site locations. One of the main advantages of chained analysis, beyond automating or semiautomating an analytical process, is the repeatability of the results and the ability to share a complex workflow with other researchers, who may not be as technologically savvy, in a way that is easy to use.

Predictive Modeling

Predictive modeling is a useful tool in archaeological investigation that is typically based on multivariate input leading to estimates of settlement distribution, human behavioral trends, and/or archaeological site locations. Predictive modeling has been helpful to archaeologists because of the time and financial limitations that exist for nearly every project. Archaeological landscapes can be vast, making ground-based inspections costly. As geospatial datasets have become more accessible and sophisticated, researchers have experimented with modeling site locations to minimize cost.

Emerging from the needs of cultural resource management firms, the central objective of predictive modeling has been to locate high-probability areas that may contain archaeological sites, which could affect modern planning projects. As a trend, high-probability areas identified by predictive models are designated high priorities for field investigation. Low-priority areas are not necessarily eliminated as prospective archaeological sites, but might require further investigation; these areas would simply not be identified as having an urgent need for investigation without considering additional information. With reliable site prediction, time and funds can be allocated to areas that are likely to contain archaeological sites – a potentially significant way to save resources, if done well. While not universally popular among archaeologists, predictive modeling has been continually explored for the past 50 years, with increasing sophistication of various approaches and degrees of reliability.

Predictive modeling has been used throughout the world, but with a particular emphasis on two areas: the British Isles (Siart et al., 2008) and North America (Chen et al., 2013; Custer et al., 1986; Saturno et al., 2007). In many cases, satellite spectral imagery, airborne laser scanning, ground-penetrating radar, and/or synthetic aperture radar are used, sometimes in combination with each other or with a GIS to inform a predictive model (Clark et al., 1998; Custer et al., 1986; Saturno et al., 2007; Siart et al., 2008). Models have been used to explore regional cultural distribution (Clark et al., 1998; Siart et al., 2008), settlement location (Custer et al., 1986; Graves, 2011; Saturno et al., 2007; Vaughn and Crawford, 2009), and ancient human movement (White and Barber, 2012; Whitley and Hicks, 2003), just to name a few applications.

A variety of multivariate statistical methods have been used to derive predictive models including logistic regression (Custer et al., 1986; Graves, 2011; Vaughn and Crawford, 2009), multiple linear regression (Kohler and Parker, 1986), and linear discriminant analysis (Chen et al., 2013). Some models do not rely on statistical methods, but instead combine datasets to narrow site potential based on the presence of visible patterning between them, or through variable scoring systems based on predefined criteria of site suitability. Sometimes statistical tests are performed on these scored data (Dorshow, 2012; Graves, 2011). Scoring methods depend on the visual interpretation of data by the researcher; the accurate assessment of which rely, presumably, on experience. Currently, archaeologists seem to be in favor of using weighted scoring systems over statistical methods, but example case studies of both can be found in the literature.

The importance of verifying data quality before analysis and following up with ground truth fieldwork cannot be overstated. Predictive models are only as good as the data analyzed, the methods used to interpret those data, and calibration to reality, but in general, model building is an adaptable process that offers the freedom to constantly explore new variables that might improve a model. As statistical and geospatial analytic methods become more integrated within archaeology, data collections become more widely accessible to researchers, and geospatial analysis programs become more sophisticated through time, predictive models will continue to become more coherent and useful to archaeologists.

Agent-Based Modeling

Last, but not least, is spatially explicit agent-based modeling, which is a technique designed to help archaeologists gain insights into the workings of complex adaptive systems (i.e., societies). Originally built for exploring interactions between particles, insects, and even herds of animals and flocks of birds, it is starting to enjoy widespread use in archaeology. Each 'agent' is a person, household, village, etc., that makes decisions based on a programmed set of rules. As simulated agents interact with one another in space and time, their decisions form a complex, nonlinear path toward a set of outcomes that can then be compared to what is known through the archaeological record. By running lots of models with variations in the rules, not only can existing hypotheses be tested, but new ones can be generated. At present, there are two main software suites for agent-based modeling that are used by archaeologists: NetLogo and Repast.

Conclusion

Recent advances in geospatial technology, and the sophisticated analytical methods that come with it, have revolutionized how archaeologists conduct fieldwork and make sense of the data they collect. With that said, archaeologists have always thought about their research problems both spatially and visually, so many of the topics discussed above can be viewed as extensions of established practice. As costs come down and barriers to entry are lowered, a broader swath of the discipline will embrace geographic information science – hopefully as full contributors, not just consumers. Archaeologists have a unique perspective on the complex relationship between people, space, and time that could benefit many other fields.

Geriatric Psychiatry

Abstract

Geriatric psychiatry is the subspecialty of psychiatry that deals with mental health in older persons. Its importance is growing due to the aging of populations worldwide. The practitioners of geriatric psychiatry are physicians working in close collaboration with other medical and nonmedical professionals and carers. The principal mental health problems covered by geriatric psychiatry are cognitive disorders, such as the dementias and delirium, and affective disorders, such as depression. While pharmacological and nonpharmacological treatments exist for the majority of disorders encountered in geriatric psychiatry, their efficacy is often limited. Further research is needed to develop more effective strategies for treatment and prevention and decrease the burden associated with mental illness in the elderly.

Scope

Geriatric psychiatry (also referred to as old age psychiatry, psychogeriatrics, gerontopsychiatry, geropsychiatry) is the subspecialty of psychiatry dealing with mental health in the elderly. Geriatric psychiatry covers the prevention, diagnosis, acute and long-term treatment, rehabilitation, and palliative care of mental illness in this population. To qualify for geriatric psychiatry services, the most frequently applied age limit is 65 years. In principle, the users of geriatric psychiatry services fall into two categories: First, persons who suffer from mental illness throughout their lives and continue to need psychiatric assistance in old age (e.g., for treatment of schizophrenia, depression, anxiety disorders). Second, persons who become mentally ill during their old age (e.g., Alzheimer's disease, late-onset depression). Certain diseases like early-onset forms of dementia may be treated by geriatric psychiatry also in patients younger than 65.

Conceptual Background

As part of medicine, geriatric psychiatry is organized as other medical specialties. Its practitioners are physicians who have first studied medicine, then specialized in general psychiatry and then subspecialized in geriatric psychiatry. However, geriatric psychiatry does not exist as a separate specialty in many countries and training in geriatric psychiatry varies considerably between countries (Camus et al., 2003; Toot et al., 2012). As subspecialty of psychiatry, geriatric psychiatry follows the biopsychosocial model (Engel, 1977), which emphasizes the contribution of biological, psychological, and social factors to mental well-being and illness. Consequently, geriatric psychiatry uses approaches from all three of these areas to improve mental well-being. Recently, the biopsychosocial model has been complemented by a focus on recovery and person-centered care (Hill et al., 2010; Daley et al., 2013), which emphasizes patient empowerment and care provision according to individual health needs and priorities. Like in other fields of psychiatry, neuroscientific research continues to have a major impact in geriatric psychiatry by improving the understanding of disease mechanisms and introducing novel diagnostic and therapeutic tools. In 2009, the Section of Old Age Psychiatry of the World Psychiatric Association (WPA) identified the respect for autonomy, beneficence/nonmaleficence, justice, and veracity as ethical principles of care for mental illness in the elderly (Katona et al., 2009). The statement endorses the human rights of older people with mental illness and takes a stand against ageism, discrimination, and stigmatization.

Development of the Field

While care for mental health problems of the elderly has existed for much longer, geriatric psychiatry as distinct subspecialty of medicine has only developed recently. Around 1900, important foundations for the field were laid by the neuropathologic findings of Alzheimer, Pick, Binswanger, and others. However, in the UK, elderly care developed into a focus of psychiatric research and clinical practice only in the 1930–1950s. Facilitating factors were requisitioning of mental hospital beds for military purposes, employment of the traditional nonprofessional caregivers – women – in the military industry, and increasing life expectancy of the older population strata (Hilton, 2005). Neuropsychiatric assessment scales were applied to measure function and Alzheimer's disease was recognized as disease of the elderly – and not as a disease of middle age as in the first case described by Alzheimer. Most importantly, mental illness in the elderly was begun to be considered not a mere consequence of normal aging (Hilton, 2005). Consequently, the first inpatient geriatric psychiatry wards were set up approximately at the same time as geriatric medicine established itself as an independent specialty. Following the rise in research in the field, international peer-reviewed journals specifically dedicated to geriatric psychiatry were established, including the International Journal of Geriatric Psychiatry (1985), International Psychogeriatrics (1989), and the American Journal of Geriatric Psychiatry (1993) (Meyers and Jeste, 2010). Formal criteria for geriatric psychiatry training were introduced in the UK in 1989, the US in 1993, Canada in 1994, Ireland in 1995, and in

 http://dx.doi.org/10.1016/B978-0-08-097086-8.27031-1

Australia and New Zealand in 1999. In Continental Europe, geriatric psychiatry was only introduced as independent specialty after 2000 (UEMS Section of Psychiatry, 2014). The principles of old age psychiatry were finally laid out by the World Health Organization (WHO) in 1996: A consensus statement on 'Psychiatry of the Elderly' was issued together with the Section of Geriatric Psychiatry of the WPA and other stakeholder organizations that covers the definition of geriatric psychiatry, its treatments, service organization, and training requirements (World Health Organization, 2001).

Professional Organizations

In many countries there are now professional organizations in which the practitioners of geriatric psychiatry are organized, e.g., the American Association for Geriatric Psychiatry. International organizations include the European Association of Geriatric Psychiatry, Section of Geriatric Psychiatry of the European Psychiatric Association, International Psychogeriatric Association, and the Section of Old Age Psychiatry of the WPA. Beyond these professional associations that primarily have physicians in the field as their members, there is a wide variety of other stakeholder organizations that usually center on specific diseases and are organized following a charity model (e.g., the Alzheimer's Association in the US).

Importance

Due to improved social and medical conditions, more people worldwide live into old age than ever. According to the WHO (World Health Organization, 2012b), the number of people aged 60 doubled between 1980 and 2012. The number of people aged 80 will almost quadruple to 395 million between 2012 and 2050. For the first time in history, the number of adults aged 65 and over will soon outnumber children under the age of 5. The majority of older people already now live in low- or middle-income countries. By 2050, this number will have increased to 80%. Consequently, an increasing number of persons falls into the age group treated by geriatric psychiatry. Furthermore, there is a particularly steep increase in the number of nonegarians (90+ years old) and centenarians (100+ years old), i.e., the very old. Special patient populations such as chronically medically ill patients, users of illicit substances, or prison inmates now also reach old age and may require psychiatric attention. At the same time, many of today's elderly people are more healthy and lead more active lives than ever before and try to conserve their abilities and lifestyle as long as possible. As a consequence, there is a high interest in preventing mental illness and improving psychiatric care in the elderly, as psychiatric disorders such as depression and dementia are associated with high levels of disability and burdens of disease (Murray et al., 2012).

While the number of elderly people is rising, the number of people in younger age groups is declining in many populations worldwide. Furthermore, with the current increase in national and international mobility, many younger people do not live close to their parents or grandparents anymore. Both trends exert pressure on the organization of care: Professional caregivers may have to take over a larger share of elderly care, but fewer people have to shoulder the cost of care and fewer professional caregivers are available for demographic reasons. Current strategies to address this problem are task shifting to nonmedical professionals (Bartels and Naslund, 2013), the improvement of working conditions, remuneration and academic standing of nursing staff, international recruitment of health care professionals, increased use of lay volunteers, and introduction of technology including robotics into the care process. However, none of these approaches is likely to fully compensate for the increasing demand for elderly care, so that there is urgent need for research and innovation that may delay the onset of need for care and facilitate independent living until higher age.

Demographic Change and Risk for Dementia

The impact of population aging on mental health is especially visible in the case of dementia, since old age is an important risk factor for the development of dementia. The prevalence for those aged 60 years and older is 5–7% in most world regions, with a higher prevalence in Latin America (8.5%) and a lower prevalence in sub-Saharan Africa (2–4%). The prevalence approximately doubles with every 5 years in age and reaches 40% or even more of all persons >90 years of age. In 2010, an estimated 35.6 million people lived with dementia worldwide. Almost a doubling of the worldwide number of dementia cases is expected every 20 years and while in 2010 58% of all people with dementia lived in low- and middle-income countries, this proportion may rise to 71% in 2050 (Prince et al., 2013). The total worldwide costs of dementia – including for informal caregiving – were estimated to be US$604 billion in 2010, which is equivalent to 1% of the world's gross domestic product (Wimo and Prince, 2012). For the US, the costs associated with dementia were calculated to be similar to the cost associated with cancer or cardiovascular disease (Hurd et al., 2013). Due to the strain for health care systems that is associated with dementia, the WHO recognized it as a public health priority in 2012 (World Health Organization, 2012a).

Some authors suggest that up to 50% of dementia cases are attributable to preventable risk factors (Barnes and Yaffe, 2011). Recent evidence indicates that the prevalence of dementia per age group is indeed declining in high-income countries, supposedly due to the protective effect of education and primary and secondary prevention of cardiovascular disease (Matthews et al., 2013; Christensen et al., 2013). Low- and middle-income countries seem to undergo the opposite trend (Prince et al., 2013; Chan et al., 2013), possibly because risk factors for dementia such as obesity and diabetes are on the rise in these countries. Harnessing the benefits of prevention may thus be crucial to decrease the health care burden associated with dementia, but will also be important in other mental illnesses in old age such as depression, delirium, or substance abuse.

Delivery of Care

The majority of mental health care for the elderly is performed by primary care physicians, geriatricians, and general

psychiatrists, while specialist care by geriatric psychiatry is usually only started after referral from primary or secondary care. Similar to other medical fields, geriatric psychiatry services are delivered in hospitals, in outpatient clinics, through consultation and liaison services, and in community services. In a consensus statement, the WHO and WPA defined good quality care for older people with mental health problems (World Health Organization, 1998). According to this consensus statement, quality geriatric psychiatry services are characterized by comprehensive, accessible, responsive, individualized, transdisciplinary, accountable, and systemic care ('CARITAS'): "A comprehensive service should take into account all aspects of the patient's physical, psychological and social needs and wishes and be patient-centered. An accessible service is user-friendly and readily available, minimising the geographical, cultural, financial, political and linguistic obstacles to obtaining care. A responsive service is one that listens to and understands the problems brought to its attention and acts promptly and appropriately. An individualized service focuses on each person with a mental health problem in her/his family and community context. The planning of care must be tailored for and acceptable to the individual and family, and should aim wherever possible to maintain and support the person within her/his home environment. A transdisciplinary approach goes beyond traditional professional boundaries to optimize the contributions of people with a range of personal and professional skills. Such an approach also facilitates collaboration with voluntary and other agencies to provide a comprehensive range of community-orientated services. An accountable service is one that accepts responsibility for assuring the quality of the service it delivers and monitors this in partnership with patients and their families. Such a service must be ethically and culturally sensitive. A systemic approach flexibly integrates all available services to ensure continuity of care and coordinates all levels of service providers including local, provincial and national governments and community organizations (World Health Organization, 1998)."

Following the CARITAS principle and the general trend for deinstitutionalization of psychiatry, current geriatric psychiatry emphasizes person-centered care in the community. Still, many elderly persons with or without mental health problems live in long-term care facilities, such as residential care or nursing homes. Delivery of care in institutions – albeit not hospitals – therefore remains an important part of geriatric psychiatry.

For delivery of care, specialists in geriatric psychiatry work in close collaboration with other medical and nonmedical professionals. In the medical field, the closest links exist with general medicine, geriatrics, neurology, and palliative care medicine. Other professions that are major constituents of the geriatric psychiatry care process are nursing, (neuro-) psychology, psychotherapy, social work, physical therapy, as well as other nonmedical therapeutic professions. The involvement of family members in the care process is often essential. Due to their medical background and understanding of mental health and old age, geriatric psychiatrists have a central role in planning of such multidisciplinary care and in assuring its continuity.

Mental Disorders in Old Age

In principle, all mental disorders encountered in younger patients can also be found in the elderly. Frequent mental disorders in old age include dementia, depression (Unützer and Park, 2012), anxiety disorders (Blay and Marinho, 2012), and substance abuse (especially the abuse of prescription medications and alcohol (Wang and Andrade, 2013)). Old age is also an important risk factor for suicide (J. Chan et al., 2007), so that assessment and treatment of suicidality is a priority. Other mental disorders such as schizophrenia or bipolar disorder rarely have their onset in old age, but may continue to be active throughout life. A special toll on mental health in the elderly is taken by neurodegenerative diseases such as Alzheimer's disease, Parkinson's disease, or one of several types of frontotemporal dementia. The prevalence of certain mental disorders like autism spectrum disorders, which are more readily associated with younger age is unknown for old age. The frequent comorbidity with medical disease in the elderly (e.g., diabetes, cardiovascular disease) may aggravate mental disorders but also cause mental illness itself, e.g., in the case of vascular dementia (Iadecola, 2013) or delirium (Inouye et al., 2014). Medical comorbidity can also lead to polypharmacy, which increases the risk for medication interactions and adverse events.

As part of the diagnostic routine in geriatric psychiatry, standardized assessments are used that cover the most important psychiatric, general medical, and social health needs in the elderly (Elsawy and Higgins, 2011). Areas that are frequently assessed in this process are cognition, mood, functional capacity, physical health, fall risk, nutritional status, dental status, continence, sexual function, sensory function, medications, living situation, financial situation, social support, spiritual needs, advanced care preferences, and goals of care. Treatment outcomes of patients who undergo such comprehensive geriatric assessment were consistently shown to be better (Ellis et al., 2011). In most countries worldwide, clinical diagnoses in geriatric psychiatry are currently made according to the International Statistical Classification of Diseases and Related Health Problems version 10 (ICD-10) issued by the WHO or according to the Diagnostic and Statistical Manual of Mental Disorders version 5 (DSM-5). Certain disorders may present differently in old age than they do in younger people, e.g., depression or personality disorders. Since ICD-10 and DSM-5 do not encompass specific old age diagnostic criteria for some of those, the diagnostic fit may not be optimal at all times and ultimately relies on clinical expertise. For research purposes, diagnoses in geriatric psychiatry are sometimes made according to criteria other than ICD-10 or DSM-5. Especially for diseases leading to dementia (e.g., Alzheimer's disease, Lewy Body diseases), the diagnostic procedure in research increasingly involves advanced neuroimaging techniques or other biomarkers that help to detect disease phenotypes before the onset of the clinical dementia syndrome.

Based on the assessment, the diagnosis, and the individual goals of care, a treatment plan is made through shared decision making between patient and physician. Frequently in geriatric psychiatry – especially in persons with advanced dementia – decision-making capacity is impaired so that treatment decisions are taken together with health care proxies, usually either

family members of professional proxies. Due to the complexity of health needs in the elderly, treatment plans often involve interventions in multiple areas and by multiple professions. Available psychiatric treatments include pharmacological (primarily medications with antidepressant, antipsychotic, mood-stabilizing, or sedative action) and nonpharmacological interventions (among others, psychoeducation and various forms of psychotherapy, but also biological therapies like electroconvulsive therapy or bright light therapy). To avoid immediate harm to self or others, involuntary treatment is sometimes necessary in severe mental disorders. Involuntary treatments include application of sedative medications and use of physical restraints and are tightly monitored, short-term emergency measures. Many mental disorders in old age are underdiagnosed ('diagnostic gap') and affected persons may not receive adequate treatment ('treatment gap'). Insufficient diagnosis or treatment may be due to lack of resources (including lack of specialized services), stigma of mental illness, but also due to the pervasive misconception that certain mental disorders are inherent part of aging (e.g., dementia).

Research

Research continues to contribute substantially to our understanding of disease mechanisms, diagnosis, and treatment of mental illness in the elderly. An especially active field is the research on neurodegenerative diseases such as Alzheimer's disease. Several lines of evidence suggest that the disease process in Alzheimer's disease starts decades before the diagnosis of dementia (Jack et al., 2013). Consequently, current clinical Alzheimer's research focuses on the development of biomarkers such as radioactive tracer molecules for neuroimaging and biochemical blood or cerebrospinal fluid assays for the detection of proteins that are presumed drivers of the disease process and may thus be suitable markers for early detection. With the increasing possibility for early detection, both pharmacological and nonpharmacological studies are now under way to test the possibility for prevention of the full-blown clinical dementia syndrome.

Still, important gaps remain in our understanding of mental illness in the elderly, and the overall evidence-base in geriatric psychiatry is lagging behind other medical fields. An important contributing factor to this deficit is the exclusion of participants from many clinical trials based on their higher age or medical comorbidity. Furthermore, study inclusion may be more difficult to perform for persons who lack capacity to give informed consent. However, according to a consensus statement by the WPA Section of Old Age Psychiatry, "older people with mental illness should have the right (and be given the opportunity) to participate in research, even if they lack capacity (Katona et al., 2009)." Open questions in the field of geriatric psychiatry include: Are common mental disorders like depression or schizophrenia in old age mechanistically different from young age? What are the shared disease mechanisms that convey risk for medical diseases like diabetes and mental disorders like depression and dementia? Can accurate and reliable diagnostic tests based on the biological disease process be established? Can strategies for prevention of mental illness in the elderly be identified and introduced into clinical practice? How can impaired cognition be restored? What are the active ingredients in nonpharmacological interventions for mental illness in old age? What defines recovery in elderly people with mental illness? How can stigma be reduced and social participation of elderly people with mental illness be improved? How can the growing need for care of elderly people with mental illness be met – particularly in the light of demographic change in low- and middle-income countries?

Gesture in Linguistics

David McNeill, University of Chicago, Chicago, IL, USA

© 2015 Elsevier Ltd. All rights reserved.
This article is a revision of the previous edition article by S. Kita, volume 9, pp. 6215–6218, © 2001, Elsevier Ltd.

Abstract

Gestures touch classical linguistic themes, especially what can be called the dynamic dimension of language. The article begins by describing a continuum of gesture kinds, and then zeroes in on co-expressive, speech-synchronized 'gesticulations.' The rest of the article describes how gesticulations exhibit and 'fuel' language dynamics in growth points, psychological predicates, catchments and prosody, material carriers and communicative dynamism, the social context of speech, and 'new' actions.

As a field of study, gesture has become energized in recent years. There is now an organization (International Society for Gesture Studies) and a journal (*GESTURE*, Adam Kendon and Cornelia Müller, founding editors). (A web page describing the Society and *GESTURE* is at http://www.utexas.edu/coc/cms/International_House_of_Gestures/.) In preparing this article, I have aimed to balance the empirical basics of gestures with a theoretical perspective from which to regard gestures and see what insights they bring to an understanding of the nature of language.

The word 'gesture' covers a multiplicity of communicative movements, primarily but not always of the hands and arms. Often, gestures are assumed to comprise a channel distinct from speech, but careful investigation challenges this traditional view. Gestures and language are best thought of as a single system, larger than either language or gesture as traditionally assumed. The aspects of gesture I shall emphasize for their importance to linguistics and the dynamic dimension of language is called 'gesticulation.' The hallmark of gesticulation (as opposed to emblems or pantomimes) is that it and speech are synchronous and co-expressive of the same idea units. 'Co-expressive' is not redundant; gesture can express its own aspect of the shared idea unit, but it and speech are expressing the same underling idea. I will give examples below.

The Dynamic Dimension

A prominent aspect of gesture, important for the study of language, but likely to be overlooked, is its relation to the dynamic side of language. Gestures not only provide a window into language dynamics but, in some interpretations, are the engine of it. Without gestures, in this view, language is a crystal palace, but uninhabited.

Speaking is more than uttering speech sounds with meaning; more deeply it is 'inhabiting' language (a term from Merleau-Ponty, 1962). Gesture is a part of how this multilayered inhabitance takes place. The dimensions have classically been called 'linguistic' and 'psychological' but better (and less proprietary) terms are static and dynamic. Some phenomena are accessible or prominent on one dimension, others on the other, but the dynamic and static dimensions cannot be isolated: they intersect and interact. The dimensions are structured on different principles and draw on different methods of description and analysis (the field of linguistics specializing on the static dimension). Yet, both are dimensions of language, and to explain the origin of language we must understand how they work together.

- The static dimension is classically accessed through the synchronic method. Language in this method is viewed as a totality at a single theoretical instant. Saussure (1959) argued that only in this way, with the whole of language laid out panoramically, could the contrasts be discerned that define *langue* (the 'systematic' aspects of a given language) and the linguistic values of words and larger constituents that contrasts generate (and two kinds of value – the syntagmatic on the axis of combination (Jakobson, 1960) and the paradigmatic on the axis of selection). "In language," Saussure said, "there are only differences" (he offered words to illustrate the concept but it applies to phrases and full sentences as well). To use Saussure's example, in English sheep on the hoof versus sheep cooked contrasts lexically, 'sheep' versus 'mutton.' French has no lexical contrast at this point – both states are 'mouton.' The words in the two languages therefore translate each other in one sense, but have different values, necessarily so because value is difference, and 'sheep' and 'mouton,' despite translating each other, differ in their internal-to-*langue* contrasts (speakers of course can distinguish the two kinds syntactically, as in 'viande de mouton'). (Thanks to Gonia Jarema for this example.) Difference and linguistic value are the foundation of the static dimension ('static' does not mean 'stasis' – we are not speaking of moments of repose between bursts of activity: every linguistic event can be regarded statically or dynamically or, as here, both).
- The dynamic dimension could be termed the 'activity' of language but I am calling it (again invoking Merleau-Ponty) 'inhabiting' language with one's being, thought, and action. This terminology has the advantage of alluding to both *langue*, the static system synchronically revealed, and to whatever animates it, the dynamic dimension. A historical figure associated with language so regarded dynamically is Vygotsky (1987). On the dynamic dimension, units come and go, emerge and disperse in real time. It crosses at 90° the abstractions from time and the unmoving totality of synchronic *langue*.

The concept of competence (as in Chomsky, 1965) aligns with Saussurian *langue*, the system of language, but with the difference that 'competence' attributes the system of language to the individual as a personal property whereas *langue* is what Saussure called a "social fact," a socially constituted set of norms. These definitions are not contradictory but take different perspectives on the same linguistic forms.

Parole and 'performance,' the other terms from Saussure and Chomsky, respectively, are defined in relation to their own static counterparts. The formula is *langage* minus *langue* = *parole* (where *langage* is the semiotic totality of language). So *parole* is the 'non-systematic' part (i.e., what remains after subtracting the systematic part or *langue*) of *langage*. 'Performance' taps a different metaphor. It is the 'use' of competence (the static totality of language in a personal knowledge base) subjected to the shortcomings of memory, attention, etc. that are irrelevant to competence. 'Use' indeed belongs on the dynamic dimension but is not the same as 'inhabiting' language with one's imagery and thought. Performance (the technical concept) is the attempt to deploy competence. Inhabitance (our concept) is not 'deploying' – an inappropriate manipulative metaphor – but 'living in' and 'through' language. An imagery–language dialectic is neither 'subtraction' nor 'use.' It is a positive process of its own that requires *langue*/competence (as one pole of the dialectic) but does not derive from it. Linguistic form (regarded either as *langue* or competence) and imagery are both necessary and are equally part of the dialectic.

The Gesture Continuum

To begin, we need to distinguish different kinds of gesture. Not all gestures are included. As mentioned, we focus on one kind, but it is important to understand the others. Adam Kendon once distinguished gestures of different kinds along a continuum that I nicknamed "The Kendon's Continuum" (McNeill, 1992), but now, at his request, have renamed the 'Gesture Continuum.' The gestures we are concerned with are the 'gesticulations.'

'Gesticulation' is motion that embodies a meaning relatable to the accompanying speech. Gesticulation is by far the most frequent type of gesture in daily use and it covers many variants and usages. It is made chiefly with the arms and hands but is not restricted to these body parts – the head can take over as a kind of third hand if the anatomical hands are immobilized or otherwise engaged, and the legs and feet too can move in a gesture mode. In a large sample of gestures, Shuichi Nobe found that the stroke phase of the gesticulation is synchronous with the co-expressive speech about 90% of the time (gesture phases are defined below). When strokes are asynchronous, they slightly precede the speech to which they link semantically, usually because of brief hesitations, and the time gap is small. Gesticulations rarely if ever follow their co-expressive speech (Kendon, 1972). There is no basis for the assertion that strokes occur during hesitations. Such view has attained urban legend status, but it is based on a misrepresentation of the original study by Butterworth and Beattie (1978). They reported that the rate of gesture occurrence was higher during speech pauses than phonations. However, far more gestures occur during phonation than pauses, so the 90% figure results (Nobe also did not replicate their higher gesture rate during pauses, possibly because of different communicative situations: Nobe was looking at narrations, while Butterworth and Beattie had analyzed college tutorials, where gestures during pauses are likely to have had 'turn-suppression' functions not prominent in narrations). The expression 'co-expressive speech and gesture' is explained below. Other controversies have revolved around the issue of whether gesticulations are communicative – 'made for the listener' – or beneficial primarily for speech production – 'made for the speaker' (cf Krauss et al., 2000; Alibali et al., 2000). Gesticulations combine both 'universal' and language-specific features. Speakers of every language studied thus far (and this is a sizable list: in our lab alone, besides English, Japanese, Mandarin, Korean, Spanish, French, German, Italian, Turkish, Georgian, Russian, ASL, Taiwanese Sign Language, and a few African languages) produce them, and the gesticulations for the same events in a cartoon stimulus show clear similarities across these languages. Yet, there are also striking differences which are traceable to characteristics of the languages the gestures are co-occurring with, in particular whether the language is, in Leonard Talmy's typology (Talmy, 2000), S-type or V-type (see McNeill and Duncan, 2000). Gesture space is oriented in terms of absolute compass direction by speakers of Guugu Yimithirr (an aboriginal language with obligatory absolute orientation in its verb morphology) and also speakers of Tzotzil (a Mayan language that lacks the lexical precision of directional reference as seen in Guugu Yimithirr, but whose mode of living promotes exact spatial orientation, which is then embodied in gestures; see John Haviland, 2000).

'Speech-framed gestures' are part of the sentence itself. The term is from Karl-Erik McCullough. Such gestures occupy a slot in a sentence, e.g., "Sylvester went [gesture of an object flying out laterally]," where the gesture completes the sentence structure. These gestures time differently from gesticulations – they occupy a gap that fills a grammatical slot, rather than synchronizing with speech that is co-expressive.

'Emblems' are conventionalized signs, such as thumbs-up or the ring (first finger and thumb tips touching, other fingers extended) for 'OK,' and others less polite. Kendon prefers the term 'quotable gesture,' referring to a potential to be quoted as a gesture, like a word – 'OK' translating into terms of approbation for example. Emblems or quotable gestures are culturally specific, have standard forms and significances, and vary from place to place. Kendon (1995, 2004) has for some years studied the gesture culture of Naples, a locale with an exceptionally rich repertoire of quotable gestures (cf de Jorio, an early nineteenth-century figure, in Kendon, 2000). These gestures are meaningful without speech, although they also occur with speech. They function like illocutionary force markers, rather than propositions, the mode of gesticulation, and when they occur they time with speech quite differently. A single Neapolitan emblem for 'insistent query' (the 'purse' or *mano a borsa*: prototypically, the hand palm up, the fingers and thumb loosely bunched together at the top, and rocking up and down) was observed in one case stretching over several utterances and then continuing into the next speaker's turn, still demanding clarification. This gesture is not employed in North America (a similar looking gesture is used to mean that

something is 'precisely so'), which illustrates the cross-cultural variation of the emblem. Emblems can blend both sequentially and simultaneously with gestures of other kinds. Many emblems have deep historical roots, far outlasting the spoken languages with which they occur. Some go back to Roman times (Morris et al., 1979), including the infamous 'finger,' beloved of the American road – it would have been understood by Julius Caesar. Most emblems have iconic or metaphoric components. The contact of the thumb and forefinger in the 'OK' sign captures the idea of precision. But the emblem is also specified by a convention pairing the form of the gesture to the approbation meaning. The fixity of the emblem is the evidence of this. Putting the *second* finger in contact with the thumb is still precision but no longer is the 'OK' sign of approbation.

'Pantomime' is dumb show, a gesture or sequence of gestures conveying a narrative line, with a story to tell, produced without speech.

And at the other extreme of the Continuum

'signs' are lexical words in a sign language such as ASL. Sign languages have their own linguistic structures, including grammatical patterns, stores of words, and morphological patterns. The linguistic code of ASL is quite unlike that of English. Sign languages have evolved without the requirement of being coordinated with speech. In fact, hearing signers find producing speech and signs simultaneously to be disruptive to both. For an authoritative description, see Liddell (2003).

As one moves along The Gesture Continuum, two kinds of reciprocal changes occur. First, the degree to which speech is an obligatory accompaniment of gesture *decreases* from gesticulation to signs. Second, the degree to which a gesture shows the properties of a language *increases*. Gesticulations are obligatorily accompanied by speech but have properties unlike language. Speech-framed gestures are also obligatorily performed with speech, but relate to speech in a different manner – sequentially rather than concurrently, and in a specific linguistic role. Signs are obligatorily *not* accompanied by speech and have the essential properties of a language. Clearly, therefore, gesticulations (but not the other points along The Gesture Continuum) combine properties – gesture with language – that are unalike, and this combination occupies the same communicative instant. A combination of unalikes, at the same time, is a key psycholinguistic fact and a framework for an imagery–language dialectic. The remainder of this article focuses on gesticulations. If no ambiguity results, from here on I shall use the simpler term 'gesture.'

Traditions of gesture study not summarized in this article because of length are gestures of the theater (Fischer-Lichte, 1992), histories of gesture studies (Bremmer and Rooddenburg, 1991), 'neurogestures' (McNeill, 2005), gestures in human–computer interface design (Wachsmuth et al., 2008), methods of gesture transcription and measurement (Quek et al., 1999), and the gestures of children (Bates and Frederic, 2002), including home signs (Goldin-Meadow, 2003).

The Iconic, Metaphoric, Deictic, Beat Quartet

These categories, or as I will say, dimensions are inspired by the semiotic categories of C.S. Peirce. Elena Levy and I (1982) proposed a classification scheme with four categories: *iconic*, *metaphoric*, *deictic*, and *beat*. All are gesticulations or speech-framed gestures on The Gesture Continuum.

Iconic

Such gestures present images of concrete entities and/or actions. For example, appearing to grasp and bend back something while saying "and he bends it way back." The gesture, as a referential symbol, functions via its formal and structural resemblance to event or objects.

Metaphoric

Gestures are not limited to depictions of concrete events. They can also picture abstract content, in effect, imagining the unimageable. In a metaphoric gesture, an abstract meaning is presented as if it had form and/or occupied space. For example, a speaker appears to be holding an object, as if presenting it, yet the meaning is not presenting an object but an 'idea' or 'memory' or some other abstract 'object' (for examples, see McNeill, 1992; Cienki and Müller, 2008; Müller, 2008). This is a gestural version of the 'conduit' metaphor that appears in expressions like 'he packed a lot into that lecture,' where the lecture is presented as a container and the message as its contents (Lakoff and Johnson, 1980). Recent work on metaphoric gestures has greatly expanded the subject. Cornelia Müller (2008) has developed a new theory of metaphor as a dynamic process (whereby 'sleeping' metaphors are 'awakened' in context) in which metaphoric gestures play an essential part. Metaphoric gestures often indicate that the accompanying speech is meta-rather than object-level – for example, saying "the next scene of the cartoon" and making a conduit cup of meaning gesture (iconic gestures, in contrast, favor the object level).

Deictic

The prototypical deictic gesture is an extended 'index' finger, but almost any extensible body part or held object can be used. Indeed, some cultures prescribe deixis with the lips (Enfield, 2001). Deixis entails locating entities and actions in space vis-à-vis a reference point, which Bühler called the origo (Bühler, 1982; Haviland, 2000). Much of the pointing we see in adult conversation and storytelling is not pointing at physically present objects or locations but is abstract pointing, which Bühler referred to as *deixis at phantasma*. The emergence of abstract pointing is a milestone in children's development. In striking contrast to concrete pointing, which appears before the first birthday and is one of the initiating events of language acquisition, abstract pointing is not much in evidence before the age of 12 and is one of the concluding events (McNeill, 1992).

Beats

It is so called because the hand appears to be beating time. Other allusions to the musical analogy use the term 'baton' (Efron, 1941). As forms, beats are mere flicks of the hand(s) up and down or back and forth, zeroing in rhythmically on the prosodic peaks of speech. This rhythmicity has made beats seem purely speech-related. However, they also have discourse functionality, signaling the temporal locus of something the speaker feels to be important with respect to the larger context. One can think of a beat as a gestural yellow highlighter.

With these four categories, Levy and I were able to classify nearly all gestures in the narrative materials we collected. Other researchers have proposed more finely subdivided categories.

But Not Kinds

I wish to claim, however, that none of these 'categories' is truly categorical. We should speak instead of *dimensions* and say: *iconicity*, *metaphoricity*, *deixis*, '*temporal highlighting*' (for beats), *social interactivity*, or some other equally unmellifluous (but accurate) terms conveying dimensionality.

The essential clue that these are dimensions and not categories is that we often find iconicity, metaphoricity, deixis, and other features mixing in the same gesture. Beats often combine with pointing, and many iconic gestures are also deictic. We cannot put them into a hierarchy without saying which categories are dominant, and in general this is impossible. A practical result of dimensionalizing is improvement in gesture coding, because it is no longer necessary to make forced decisions to fit each gesture occurrence into a single box.

Gestures 'Fuel' the Dynamic Dimension of Language

Tight Binding

The temporal binding of speech and gesture is almost impervious to forces trying to interrupt it. The very heterogeneity of the following observations shows the inviolability of the speech–gesture unit (see McNeill, 2005 for details). Tight binding is an essential feature of how gesture unleashes dynamism, its intrinsic fluidity infiltrating the static dimension and bringing it to life.

Gesture Synchrony and Delayed Auditory Feedback

Delayed auditory feedback or DAF has a dramatic effect on the flow of speech, which slows down, becomes hesitant and is subject to drawling and metatheses (Spoonerisms). Nonetheless, despite the interruptions, speech and gesture remain in synchrony.

Gesture Inoculates against Stuttering

Mayberry and Jaques (2000) made two noteworthy observations. First, the onset of a gesture stroke inoculates against the onset of stuttering. Second, if stuttering begins *during* a stroke, the speaker's hand freezes in midair and may fall to rest. In both observations, we see an incompatibility between the interruption of speech in stuttering and the occurrence of the meaningful gestures.

Gestures of the Blind

Congenitally blind speakers, who have never observed gestures, nonetheless do gesture and do so as frequently as sighted subjects, and gesture even when they know that they are talking to another blind person (Iverson and Goldin-Meadow, 1998). This is dramatic evidence of a speech–gesture bond.

Information Exchange

Information received in a gesture may be recalled later as speech (not gesture) (Cassell et al., 1999). Symmetrically, Kelly, et al. (1999) observed subjects recalling information presented in speech as having been gestural.

Gestures and Fluency

Speech and gesture become complex or simple in tandem, even to the point of jointly disappearing (the gesture disappears along with speech, rather than replacing it).

To Sum Up Binding

Speech and synchronous co-expressive gestures form a tightly bound unit, capable of resisting outside forces attempting to separate them, such as DAF, stuttering, lack of visual experience of gesture, and loss of fluency. Speech and gesture also spontaneously exchange information in memory, so that when something is recalled the speaker cannot tell the original format. Tight binding clearly fosters an imagery–language dialectic by creating unbreakable psycholinguistic units within which it can take place.

Context and Psychological Predicates

Gesticulations (but not other points along the Gesture Continuum) have the property that *strokes synchronize with co-expressive speech*. This section explains this concept. Gesture–speech unity is argued to have been the starting point of language evolution in McNeill (2012). An example is illustrated in **Figure 1** but many other examples can be found. Mostly, the gestures we studied, of which **Figure 1** is an example, were collected in a standardized manner: a participant is shown an approximately 8-min long animated Tweety and Sylvester cartoon. For readers unfamiliar with the genre, Tweety is a pear-shaped, pugilistic canary belonging to an elderly, far from retiring character named Granny. Sylvester is an enterprising cat, endlessly pursuing Tweety with culinary goals, whose lot is frustration and disaster. The genre was familiar to our narrators but not the specific cartoon ('Canary Row,' Warner Brothers, 1950). The cartoon consists of eight episodes, all with the same pursuit-catastrophe theme in amusing variations. It was originally chosen by McNeill and Levy (1982) to be shown to children but most adults also

Figure 1 'Rising hollowness' gesture with: "he goe[s *up through the* pipe] this time." Computer art by Fey Parrill, now on the faculty of Case Western University. Used with permission of University of Chicago Press.

find it engaging. One participant (the 'speaker'), chosen at random, was shown the cartoon in its entirety. Immediately after viewing it, the speaker recounted the story to a second participant "as accurately and completely as possible, as your listener will have to retell the story based on your narration" (or words to this effect). The second participant was a genuine listener, not one of the experimenters (usually a friend or spouse). The performance was audio-video recorded with the speaker in full camera view and at least the front half of the listener as well. The instructions emphasized that the experiment was about storytelling and gesture was not mentioned.) The speaker was describing a cartoon episode in which one character tries to reach another character by climbing up a drainpipe on the inside. The speaker is saying, "and he tries going *up thróugh* it this time," with the gesture occurring during the boldfaced portion (the illustration captures the moment at which the speaker is saying the vowel of 'through'). Co-expressively with 'up' her hand rose upward, and co-expressively with 'through' her fingers spread outward to create an interior space. The upward movement and opening of the hand took place simultaneously, and both were synchronized with 'up through,' the linguistic package that carries the same meanings. (What Kendon (1980) called the gesture phrase – one complete "manifestly expressive action" – is enclosed within "[" and "]." In any gesture phrase up to five distinguishable phases can occur. Not all phases need be present, but one or more *strokes*, the image-bearing phase, marked in boldface, is obligatory; without it, a gesture is not said to have occurred. **Figure 1** had one stroke during 'up through.' The *preparation* phase is the hand getting into position to make the stroke and is indicated by the span from the left bracket to the start of the boldface stroke. The preparation shows that a gesture is coming into being. *Holds* are cessations of movement, either a prestroke, the hand frozen awaiting the stroke, or a poststroke, the hand frozen in the stroke's position and hand shape even though movement has ceased. Holds of either kind are indicated with underlining. Speech notations: a *slash* '/' mans a silent pause; *repeated letters* a filled pause; and an *asterisk* an interruption.)

The effect is a uniquely gestural way of packaging meaning – something like 'rising hollowness,' which does not exist as a semantic package of English at all. The gesture and the linguistic construction synchronize as a whole, not component by component. Thus, speech and gesture synchronize at the point where they are co-expressive and this, not the components, is the unit that aligns them.

Growth Points and Context

Synchronous combinations of such unlike modes of cognition – visuospatial-actional gesture synchronized with analytic-combinatoric speech – may be operative psycholinguistic units, termed 'growth points,' or GPs (McNeill and Duncan, 2000). One way to think of a GP is as imagery that is categorized linguistically, an image with a foot in the door of language. A GP is inferred from the totality of communicative events, with special focus on speech–gesture synchrony and co-expressivity. It is called a GP because it is meant to be the initial form of a thinking-for-speaking unit out of which a dynamic process of utterance and thought organization emerges.

The Psychological Predicate

Regarding the GP as a psychological predicate (a term from Vygotsky, 1987 – not always a grammatical predicate) suggests a mechanism of GP formation in which *differentiation of a focus from a background* plays an essential part.

The concept of a psychological predicate illuminates the theoretical link between the GP and the context of speaking. Defining a psychological predicate requires reference to the context; this is because the psychological predicate and its context are mutually defining. The psychological predicate:

1. Marks a significant departure in the immediate context; and
2. Implies this context as a background.

We have in this relationship the seeds for a model of real-time utterance generation and coherent text formation.

First, when gestures and speech synchronize they jointly form the contrast underlying a psychological predicate. Second, the form of the gesture embodies the content that makes this differentiation meaningful. These correspondences can be demonstrated by exploiting a quirk in the cartoon stimulus that we have employed, in which Sylvester attempts to reach Tweety by climbing a drainpipe conveniently running up the side of the building from street level to the floor where Tweety is perched; he does this twice – first on the outside of the pipe, then on the inside. If a speaker recalls both attempts and in the correct outside–inside order, the gesture–speech combination relating to the second attempt includes a focus on interiority; this is the differentiating element. If a speaker misses the outside attempt but does recall the inside attempt, or recalls them in reverse order, interiority does not now contrast with exteriority, and the gestures with such recall do not include it as a particular feature. These results have been reported by Susan Duncan at workshops; I summarize them, with illustrations, in McNeill, 2005.

Catchments and Prosody

The field of meaningful oppositions a psychological predicate differentiates can be discovered directly in the gestures themselves. We then uncover yet another form of gestural discourse cohesion. Catchments are when space, trajectory, hand shape, etc. recur in two or more (not necessarily consecutive) gestures. Catchments show the effective contextual background and provide an empirical route to the discovery of the discourse context.

- A catchment is recognized from recurrences of gesture form features over a stretch of discourse.
- It is a kind of thread of consistent visuospatial action imagery running through the discourse and provides a gesture-based window into discourse cohesion.
- The logic is that discourse themes produce gestures with recurring features; these recurrences give rise to the catchment.
- Thus, reasoning in reverse, a catchment offers clues to the cohesive linkages in the text with which it co-occurs.

Adam Kendon, in 1972, published a detailed analysis of a filmed conversation, and identified and correlated three hierarchies – kinesic, prosodic, and discursive. We can follow up on Kendon's analysis making use of the concepts of a psychological predicate and catchment. In our study (McNeill et al., 2001),

subjects were asked to describe their living quarters to an interlocutor. In one case, describing her house, the following occurred:

1. so you're in the kitchen
   n' there's a sss-
   the back stairc*
   oh I forgot to say
   when you come though the*
   when you enter the house from the front
   and you open the door with the*
   the glass in them
   there's a* the front staircase runs right up there on your left
   so you can go straight up stairs to the second floor from there if you want
   but if you come around through the kitchen into the back
   there's a back staircase that winds around like this
   and puts you up on the second floor

The following four catchments can be identified covering this passage:

C1 consists of right-hand gestures elevated above the right knee; all are associated with *the kitchen* at the back of the house. See **Figure 2(a)**

C2 consists of two-similar hand gestures; all are associated with the theme of *the front doors* of the house. See **Figure 2(b)**.

C3 consists of left-hand gestures made with the arm extended and lifted up; all are associated with *the front staircase and second floor*. See **Figure 2(c)**.

C4 consists of right-hand gestures where the hand rises and turns in a spiral motion, while the left hand remains in an elevated hold; all are associated with *the back staircase and its relationship to the second floor*. See Figures 2(d) and 2(e).

Each catchment is distinctive in form, location, and/or movement and has nonconsecutive occurrences. The *C2* 'front door' catchment links back to a much earlier description of the front doors of the house. The centerpiece of this discourse is the back staircase (*C4*) and its location at the back of the house where it connects the kitchen to the second floor. The first mention of the back staircase is immediately aborted ("oh I forgot to say") and is replaced by *C2* 'front door' and then *C3* 'front staircase.' *C3* is held as the kitchen *C1* and back staircase *C4* catchments resume. *C3* is hierarchically dominated by *C1*/*C4*, as we infer because it is motionless. One interpretation of the discourse is that the speaker aborted the first mention of the back staircase when she recalled that she had yet to mention another way to reach the second floor of the house that was linked to the front entrance. A repair was undertaken by introducing *C2* (the front doors, going back to the beginning of the house tour) and from there presenting the front staircase and second floor (*C3*). At the end of this repair, an overlap of catchments took place when the elevated left hand from *C3* was held, now representing the second floor, and the back staircase *C4* resumed and connected to it. The two-different hands gesture thus created an overlap of the *C3* and *C4* catchments.

The arrangement in **Table 1** shows a hierarchy of *discourse purposes* as revealed by the Nakatani et al. (1995) query procedure. Position in the hierarchy is indicated by indentation; gesture location is shown with boldface. The text is broken up so that each line is a single prosodic phrase. The numbers refer to the hierarchical level of the purpose, as determined by the procedure, which consists of asking and answering with a purpose why each line was uttered (the procedure applies only to statements that fulfill a purpose, not always the case, but here it was). The hierarchy and the discourse's catchment structure correspond closely – in fact, 100%!

Each catchment had its own purpose level or levels, not shared by the other catchments. At this degree of delicacy, there is a perfect mapping of the discourse structure onto gesture and the speaker apparently created discourse segments on the basis of consistent WHY purposes. Gestures are thus here accurately accounted for as presenting information that is relevant to the WHY? questions of the purpose hierarchy. For example, the answer to purpose 1.1 is 'in the kitchen,' and a gesture was performed that conveyed this content (the hand held in a space identified as the kitchen). Predicting gestures from purposes suggests that the WHY? hierarchy was guiding the speaker by defining what was newsworthy at each point, hence her psychological predicates, and that gestures expressed this content. The catchment is the base from which the communicative weight of the gesture is formed. Each gesture is simultaneously shaped by its semantic content and its relationship to a catchment.

Thus several dimensions converged: The catchment determined the form of the gesture – it was formed to differentiate the next step in the catchment; the utterance purpose defines the communicative weight; the gesture provides the content.

The third leg of Kendon's triad is prosody. To access this dimension, we made use of the ToBI (Tone-Break-Index) analytic system. Following Beckman and Hirschberg (1994),

Figure 2 (a). *C1* KITCHEN gesture with "so you're in the kitchen." (b) *C2* FRONT DOORS gesture with "when you enter the house." (c) *C3* front staircase/second floor gesture with "to the second floor." (d) *C4* back staircase gesture with "there's a back staircase that winds around like this." (e) *C3* + *C4* BACK STAIRCASE + SECOND FLOOR gesture with "and puts you up on the second floor." a ToBI transcription occupies four tiers: (1) orthographic transcription (as above), (2) a tone tier in which phrasal tones and pitch accents are marked, (3) a break-index tier in which juncture degree is rated between each pair of words and after the final word, and (4) a miscellaneous tier (comments by the coder). We focused on tiers (2) and (3). (ToBI coding by Karl-Erik McCullough.)

The more deeply embedded a segment in the discourse, the higher the final boundary tone, conveying a 'more is to come' meaning. The more dominant the segment, correspondingly, the lower the final tone, reflecting a declarative pattern. This contrast evidently reflects a general characteristic of intonation contours with independent and dependent content.

Prosodically, each catchment had its own distinctive boundary tone. The *C1* (kitchen) and *C4* (the back staircase) catchments, which come together at the end of the discourse in terms of the spatial layout of the house, were Low. *C2* and *C3* were preponderantly High.

What factors influence the boundary tone of a given catchment? Two seem important. One is the discourse embeddedness of the content, noted above, in which embedded content tended to have high final tones and main-line content low final tones. Iconicity is a second factor. The high and low tones seem to show semantic motivation (cf Bolinger, 1986) in that phrases having to do with the base of the stairs tended to end Low and those with the second floor High. Thus aspects of intonation behave like gestures themselves, and are predictable from knowledge of both semantic content and position in the discourse structure.

The Break Index code also shows the degree of phonological distinctiveness at each 'break' point in the speech stream, ranging from 0 for the highest degree of phonetic reduction to 4 for a full intonation phrase boundary. The *C4* catchment (the back staircase) had a high level of phonetic reduction (Level 0), reflecting more internal continuity of speech. In a seeming paradox, *C4* also had the highest proportion of full intonation phrase boundaries (Level four). The paradox is only apparent, however, and makes sense if we consider that the back staircase was the dominant catchment of the full discourse. This central position yielded tightly configured gesture-prosody packages – internal boundaries glossed over while external boundaries were maximized.

Our general conclusion is that the organization of discourse is inseparable from gesture and prosody: the three components are different sides of a single mental-communicative process. A purely text-based approach, as in the narratology tradition, is blind to two-thirds of this discourse structure. Indeed, the principal themes of the living space discourse were *gestural* – the four catchments embodied the speaker's intentions and were the foundations of the discourse purposes of successive utterances. The utterance hierarchy grew out of these images but only partially encoded them (as we see in the greater delicacy of discourse information in gesture). It was to present catchment themes that the discourse, at each moment and step by step, was organized. Prosody, the other component of the triad, is gesture in spoken form, as in Bolinger (1986). The psychological predicate is the basis for integrating all these components. It provides the co-equal generation of gesture and speech from the same semantic intent. The catchment is the locus around which this integration proceeds.

Material Carriers and Inhabitance

An abiding feature of the dynamic dimension is the creation of what Vygotsky (1987) termed material carriers – a phrase referring to the embodiment of meaning in enactments or material experiences. (Pointed out to me originally by Elena Levy. The quote (rediscovered by Tae Kunisawa) is: "That which is specific to this particular form of sound has remained unexplored. As a consequence, this research has not been able to explain why sound possessing certain physical and mental characteristics is present in human speech or how it functions as a component of speech. In a similar manner, the study of meaning has been defined as the study of the concept, of the concept existing and developing in complete isolation from its material carrier. To a large extent, the failure of classic semantics and phonetics has been a direct result of this tendency to divorce meaning from sound, of this decomposition of the word into its separate elements" (Rieber and Carton, 1987, p. 46).) The material carrier deepens insight into gesture and also into other forms of motor execution, writing something down for example, the very act of it, whatever it is enhancing the symbolization's existential power. Materialization implies that the gesture, this natural material image, the actual motion of the gesture itself,

is a dimension of meaning. Enhancement of language is possible if the gesture is the image in an imagery–language dialectic, not an 'expression' or 'representation' of it, but is it. From this viewpoint, a gesture, the global-synthetic whole, is an image in its most developed – that is, in its most materially, naturally embodied – form. The absence of a gesture is the converse, an image in its least material form. The material carrier concept thus explains how an imagery–language dialectic still is possible in the absence of gestural movement. When there is no gesture there is still imagery and a dialectic with linguistic categorization, still the simultaneous rendering of meaning in opposite semiotic modes – the dialectic in its essentials – but it is bleached, experienced at the lowest level of materialization. This leads us to expect that gestures are more elaborate, more materialized, and more frequent – more present – when the psychological predicate has greater newsworthiness.

In Figure 3 we see a range of materializations, from zero to full, on two continua – speech and gesture. "Communicative dynamism" (CD) is the extent to which a given spoken or gestured form "pushes the communication forward" (Firbas, 1971). The continua correlate positively with CD in terms of the elaboration of the quantity of 'substance' involved. The most elaborate NPs are accompanied by the most developed gestures, the least with the least. So the more discontinuous an utterance is with the previous context, the greater the CD, the more probable a gesture, the more internally complex it will be, and the more complex the synchronous speech as well.

The concept of a material carrier is raised to a whole new level when we turn to Merleau-Ponty (1962) for insight into the unity of gesture and language and what we can expect of gesture in a dual semiotic process. Gesture, the instantaneous, global, nonconventional component, is 'not an external accompaniment' of speech, which is the sequential, analytic, combinatoric component; it is not a 'representation' of meaning, but instead meaning 'inhabits' it:

> The link between the word and its living meaning is not an external accompaniment to intellectual processes, the meaning inhabits the word, and language 'is not an external accompaniment to intellectual processes.' (Merleau-Ponty's quotation is from Gelb and Goldstein (1925: p. 158).) We are therefore led to recognize a gestural or existential significance to speech.... Language certainly has inner content, but this is not self-subsistent and self-conscious thought. What then does language express, if it does not express thoughts? It presents or rather it *is* the subject's taking up of a position in the world of his meanings
>
> p. 193; emphasis in the original. (I am indebted to Jan Arnold (pers. comm.) for this quotation.)

The GP is a mechanism geared to this 'existential content' of speech – this 'taking up a position in the world.' Gesture, as part of the GP, is inhabited by the same 'living meaning' that inhabits the word (and beyond, the discourse). The correlation of speech and gesture complexity in Figure 1 thus involves greater 'inhabitance' (if this concept can be gradual, half in, half out); it involves more of the body, in movements more coordinated by the significance being differentiated from context. It is a thought–language–hand link simultaneously affecting both motor domains.

A striking illustration of materialization is Cornelia Müller's (2008) "waking of sleeping metaphors," the breath of new life given by a gesture to an inactive or 'sleeping' metaphor. It shows the effect of the gesture as a material carrier. Müller gives the example of a German metaphor ('gefunkt,' 'sparked,' the equivalent to English 'clicked,' for suddenly falling in love). The metaphor is usually inactive, experienced as an arbitrary term. However, a speaker, describing her first love, said, "between us somehow it sparked ['clicked']" (Müller's translation). As she said 'between us' her hand rose upward touching her face at eye level, in a ring shape but with an unusual orientation – the fingers pointing at her own face; then, as she uttered the metaphor itself, 'gefunkt,' her hand abruptly turned outward – her gesture materializing the 'dead' (actually,

Communicative dynamism (CD)

sleeping) metaphor as a sudden event, an electrical spark out to her loved one.

A deeper answer to the query, therefore – when we gesture, what are we doing? – is that we are updating our current cognitive being, our very mental existence, while it is occurring. By performing the gesture, a core idea is brought into concrete existence and becomes part of the speaker's existence at that moment. The Heideggerian echo in this statement is not accidental. Following Heidegger's emphasis on being, a gesture is not a representation, or is not only such: It is a form of being. From a first-person perspective, the gesture is part of the immediate existence of the speaker. Gestures (and words, etc., as well) are themselves thinking in one of its many forms – not only expressions of thought, but thought, i.e., cognitive being, itself (see Dreyfus, 1994). To the speaker, gesture and speech are not only 'messages' or communications, but are a way of cognitively existing, of cognitively being, at the moment of speaking. (The 'H-model' avoids the homunculus problem encountered by the third person perspective inherent in the concept of a 'representation' and with it the 'theater of the mind' problem highlighted by Dennett (1991). The theater of the mind is the presumed central thinking area in which representations are 'presented' to a receiving intelligence. The possibilities for homunculi – each with its own theater and receiving intelligence – spiraling down inside other similarly endowed homunculi in this theory are well known. In the H-model, there is no theater and no extra being; the gesture is, rather, part of the speaker's momentary mode of being itself, and is not 'watched.')

The speaker who creates a gesture of Sylvester rising up fused with the pipe's hollowness is, according to this interpretation, embodying thought in gesture, and this action – thought in gesture–action over the thought–language–hand link – was part of the person's being cognitively at that moment.

To make a gesture, from this perspective, is to bring thought into existence on a concrete plane, just as writing out a word can have a similar effect. There is not a causal sequence, thought → speech/gesture; speech and gesture are the thought coming into being at that instant. The greater the felt departure of the thought from the immediate context, the more likely its materialization in a gesture. Thus, gestures are more or less elaborated depending on the importance of material realization to the existence of the thought (Figure 4 again).

Social Context

Vygotsky (1987), in his debate with Piaget, famously asserted that everything appears in a child's development twice, first on the social plane, later on the psychological. The concept of a social-to-psychological transition can be applied to gestures as well. Gestures imply a social other. If one denies access to a listener, the frequency of gesture declines (Alibali et al., 2000). Increasing the number of listeners changes the shape of the gesture space and this in turn changes the direction of gestures depicting movements of characters in the story (Özyürek, 2000).

Mimicry and Gestures in Two Bodies

Gestural mimicry occurs when one conversational partner, within a short time, reproduces the gesture of the other partner; the effect is often to cement a kind of social solidarity and is accordingly seen commonly between close friends. The example in Figure 4 from research by Irene Kimbara (2006) shows the woman on the left reproducing the gesture just performed by her friend on the right.

A different kind of shared gesture is also possible between strangers. The following illustrations are from Nobuhiro Furuyama (2000) who studied the gestures of learners as they were instructed in a new motor task (*origami* paper folding). In each illustration, the learner is seated at the left (two different training sessions).

Figure 4 Interpersonal mimicry. (a and b) Speaker on the right: describing the line as 'irregular'; her gesture depicts lines of waiting passengers; the separation of her hands may depict the density of the crowding. Speaker on the left: in (b), hands entering the gesture space and preparing to perform gesture in panels c and d. (c and d) Continuous with panels a and b. Speaker on the left mimics right speaker's two-line gesture as she emphatically agrees ('yes, yes, yes, yes'), including absolute direction (in both figures, the hands are moving toward camera). Meanwhile, in (d), right speaker is preparing her next gesture. Computer art by Fey Parrill. From Kimbara (2006), a, b, c, d. Used with permission of the University of Chicago Press.

In the Figure 5(a) example, the learner mimics the gesture of her tutor. The mimicry occurred without speech by the learner, but her *gesture* synchronized with the *tutor's speech*. As the tutor said, "[pull down] the corner," the learner performed the gesture during the bracketed portion.

The Figure 5(b) example, in contrast, shows the learner appropriating the tutor's *gesture* by combining it with her *speech*. The learner is saying "[you bend this down?]," and during the bracketed speech moved her hand to the tutor's hand, and then moved her hand downward and away (the illustration shows the start of the gesture). As Furuyama observes, the tutor had turned in his chair so that the same left–right gesture space was before him and the learner, a maneuver that might have invited her to enter his gesture space. It is striking that any taboo against strangers coming into physical contact was overridden while the hands were in a symbolic mode.

Examples of these kinds address what can be called collectively the 'social resonance' of gesture. Janet Bavelas has long been interested in this phenomenon. Bavelas et al. (2000) have demonstrated resonance not from the viewpoint of shared feelings, the more traditional approach, but as joint cognition and storytelling; gestural repetition seems to act as grounding and in general conveys mutual understanding.

Gestures – Do They Stem from Practical Actions?

Speech is a 'new action' and so also is gesture, in the sense that any plausible primate antecedents have been altered by the evolution of language itself. They and speech have been unified. The origin of language brought gesture and speech together in an imagery–language dialectic, and this spawned new forms of each. Does anything remain of 'old actions' of the hands and body in this new action gesture world? Many of my fellow researchers of gesture and action consider practical actions to be the source of gestures in evolution as in daily life. Kendon regards gestures as ritualized practical actions. Streeck (2010), LeBaron and Streeck (2000), and Müller (1998) have also proposed that gestures stem from practical, world-directed actions. Kendon in his plenary talk at the Frankfurt/Oder International Society for Gesture Studies conference (2010) likens a gesture of something being flat to "*making* something flat" (p. 14, emphasis in original) and more generally, alluding to Streeck, that "many of the actions [i.e., gestures] understood as meaningful can be understood as being derived from actions of the hands acting in relation to objects in the environment" (p. 14, emphasis in original).

The idea that gestures derive from actions is plausible at first glance but there is more (or perhaps less) than meets the eye. A gesture may look like a pragmatic action but the action has changed at its core. To describe a gesture as 'outlining' or 'shaping' is useful as a description but to also say that such a practical action is still within the gesture is to disregard what makes the gesture a human sign. Our initial example, the 'rising hollowness' gesture (Figure 1), looks like the action of lifting something in the hand, but the gesture is not lifting at all. It is an image of the character rising, of the interior of the pipe through which he rose, and of the direction of his motion upward – all compacted into one symbolic form to differentiate a field of meaningful oppositions having to do with HOW TO CLIMB A PIPE: the gesture shows ON THE INSIDE. This complex idea, as a unity, orchestrated the hand shape and movement; it is the same motor response but it is not the action of lifting up an object.

While a gesture may engage some of the same movements and tap in part the same motor schemas as an 'action–action' it has its own thought–language–hand link in the brain. In keeping with the unity of speech and gesture, the manual movements of gestures as well as the actions of speech are co-opted and orchestrated in new ways by significances other than those of the original vocal tract and manual actions. We observe the separation of 'action–actions' and 'gesture–actions' directly in the IW case where, without vision, action–actions are impossible but gesture–actions are normal (see McNeill et al., 2008).

To show the difference that 'new actions' make for explaining gesture and speech, I will take, for my purposes, an especially challenging example from a talk by Cornelia Müller (at the University of Chicago, 7 May 2011). The example is challenging because, at first sight, it compellingly shows a gesture coming from an 'action–action' source. But we can also see that if there was an action–action element, it was secondary, recruited by a *sui generis* gesture that had nothing to do with the action–action but was a contrast in a field of meaningful oppositions that the speaker had created as part of speaking itself. Müller described a conversation she had filmed in which a speaker (of Spanish) first outlined an oval shape with a two-handed open-palm gesture for the shape of the wall plaque, then outlined it again with extended forefingers. Was he tracing an outline of the plaque with his fingers? In speech,

Figure 5 Embodiment in two bodies. (a) Mimicry by learner (on left). (b) Appropriation by learner (left). Computer art by Fey Parrill From Furuyama, Nobuhiro, 2000. Gestural interaction between the instructor and the learner in origami instruction. In: McNeill, D. (Ed.), Language and Gesture. Cambridge University Press, Cambridge, pp. 99–117. Used with permission of the University of Chicago Press.

he said "lo tenía *con un a marco redondo*" [lit. it he-was holding *with a frame round*]. (Thanks to Gale Stam for translation.) From a GP viewpoint, the speaker highlighted exactly the roundness of the plaque; this was the psychological predicate and GP in his immediate context of speaking. His forefingers, circling around the plaque shape, embodied the differentiation specifically of 'ROUND' in this field of meaningful oppositions (rather than the size, as in the first two-handed open-palm gesture) – something like THE PLAQUE'S RIM: ROUND. So, while the gesture looks like 'tracing,' the stroke was integrated with the synchronous speech at the point where they were co-expressive, differentiating a field of alternative possible rim-shapes. In this event, tracing fingers may not be 'tracing' (with this significance) at all but a contrast in imagery of rim-to-plane that was an integral part of speaking.

Some gestures do recreate actions; they take action stubs and ritualize them, much as Kendon described. These gestures are more than actions – they are a kind of performance, a replication of the action, and may also include posture, spatial location, as well as the manual action. These gestures are of two kinds. Some are pantomimes at their own locus on the Gesture Continuum. Others are 'character viewpoint' (C-VPT) gestures, gesticulations with the viewpoint of the character that is being recounted. And here again the difference of pantomimes from gesticulations applies; pantomime relates to speech loosely, gesticulation combines with it at the point of co-expressiveness. The C-VPTs are co-expressive with speech and their viewpoint is part of the semiotic with which they oppose it in a dialectic – a C-VPT is, among other things, *not* an 'observer viewpoint,' or O-VPT, a significance that it has but that is not part of a pantomime. Pantomime is simulated action and has no such contrastive value. In the 'it down' catchment example the speaker's hands were Tweety's hands, the space his space, her body his, and so forth – the speaker stepped into Tweety's shoes and added this to the utterance itself. It was part of a caused-motion unpacking ("… and $\varnothing_{tw}$ drops *it* (= a bowling ball) *do*wn the pipe"), making Tweety the agent. The gesture's C-VPT perspective was shaped by this caused-motion agent significance. The most telling difference from a replicated action is that, agent-wise, the hands thrust the ball down, in contrast to the deputation of this motion to gravity in the stimulus. All of this could happen because the gesture was a 'new' action, formed over the thought–language–hand link.

What looks to be an 'action–action' source of gesture is often really a metaphor in gesture form. The metaphor uses the action–action as its vehicle. The gesture embodies this vehicle but is not itself the action. It is an iconic image and in is fact two steps removed from the action. The metaphor itself is one step. Müller's (2008) awakening process adds another. (Müller views metaphor dynamically, as a *process* by which the speaker and her listener generate metaphoricity in the context of the speech event; clearly a conception in alignment with the arguments of this paper.) If there is an action source of the *metaphor* then that action can also be brought to the surface. The 'old' action circuit is activated along with the 'new' thought–language–hand circuit as a kind of meta-gesture comment. The question is whether this old action is necessarily active whenever the metaphoric gesture arises, and the answer is no. To see why, notice what happens to the metaphoric gesture when you do awaken the action. In the case of a rejection metaphor (the hand slicing side to side, palm forward, in typical form) it becomes a simulated removal of the imagined offending object (as if flicking a fly off with a finger, etc.). This action–action pantomime the metaphor co-opts into a new version of the metaphor. As a result, the action changes character; the opposite of the metaphor coming out the action. This is not to say that awakenings do not occur. They do but, to remain part of speaking rather than detaching from it, the meaning also changes; the pantomime becomes a meta-gestural layer commenting on the metaphor vehicle, as if saying that the metaphor is *decorated* with pantomime ("I am totally against your argument" plus flicking: the meta-comment of the awakened action is something like saying (if you dared), "your argument is puny, repellent and can be flicked away like a fly"). None of this shows that metaphoric gestures derive from action-actions. Quite the contrary, the gesture *recruits* the action as an ornament.

Liebal et al. (2010), following Kendon 2004, describe what they identify as 'gesture families,' which in their study are families of chimp gestures based on shared action sources – slapping, pushing, offering, etc. If these gestures are what they seem, miniaturized and ritualized editions of the source actions and not chimp metaphors, they do what human gestures do not, preserve in the gesture the original significance of the action, and would count therefore as yet another morsel of what, on comparison, arose from language evolution – new kinds of actions with their own significances that do not occur with the apes. Indeed, the key difference between ape emblems (if this is what they can be called) and human emblems is that those of apes are action stubs, while those of humans are metaphors – a precision metaphor within 'OK,' the image of a removal metaphor within 'negation,' and so forth. It all points to the mode of human cognitive action that evolution engendered.

Part of the scale, creativity and distinctiveness of human thought lies precisely in its freedom from pragmatic action constraints. When the hands make a gesture, it is thought that controls them and not a hidden action with purposes in relation to the physical world.

Abstract

Although the social sciences have made extensive use of the term 'ghetto' as a descriptive term, they have failed to forge a robust analytical concept of the same, relying instead on the folk notions taken for granted at each epoch in the society under examination. This article constructs a relational concept of the ghetto as a Janus-faced instrument of ethnoracial closure and control by drawing on the historiography of the Jewish diaspora in Renaissance Europe, the sociology of the black American experience in the Fordist metropolis, and the anthropology of ethnic outcasts in East Asia. This reveals that a ghetto is a social-organizational device composed of four elements (stigma, constraint, spatial confinement, and institutional encasement) that employs space to reconcile the two antinomic purposes of economic exploitation and social ostr! acization. The ghetto is not a "natural area" coterminous with 'the history of migration' (as Louis Wirth argued), but a special form of collective violence concretized in urban space. Articulating the concept of ghetto makes it possible to disentangle the relationship between ghettoization, urban poverty, and segregation, and to clarify the structural and functional differences between ghettos and ethnic clusters. It also enables us to spotlight the role of the ghetto as symbolic incubator and matrix for the production of a spoiled identity, and suggests that it should be studied by analogy with other institutions for the forced confinement of dispossessed and dishonored groups such as the reservation, the refugee camp, and the prison.

It is a paradox that, while the social sciences have made extensive use of the 'ghetto' as a *descriptive term*, they have failed to forge a robust *analytical concept* of the same. In the historiography of the Jewish diaspora in early modern Europe and under Nazism, the sociology of the black American experience in the twentieth-century metropolis, and the anthropology of ethnic outcasts in Africa and East Asia, its three traditional domains of application, the term 'ghetto' variously denotes a bounded urban ward, a web of group-specific institutions, and a cultural and cognitive constellation (values, mindset, or mentality) entailing the sociomoral isolation of a stigmatized category as well as the systematic truncation of the life space and life chances of its members. But none of these strands of research has taken the trouble to specify what makes a ghetto *qua* social form, which of its features are constitutive and which derivative, as they have, at each epoch, taken for granted and adopted the *folk concept* extant in the society under examination – which explains that the notion, appearing self-evident, does not figure in most dictionaries of social science, including previous publications of this encyclopedia.

A Wooly and Shifting Notion

Thus the semantic range of the 'ghetto' in American society and social science, which has dominated inquiry into the topic both quantitatively and thematically, has successively expanded and contracted in keeping with how political and intellectual elites have viewed the vexed nexus of ethnicity and poverty in the city (Ward, 1989). At first, in the latter half of the nineteenth century, the term designated residential concentrations of European Jews in the Atlantic seaports and was clearly distinguished from the 'slum' as an area of housing blight and social pathology. It dilated during the Progressive era to encompass all inner-city districts wherein exotic newcomers gathered, namely lower-class immigrants from the Southeastern regions of Europe and African Americans fleeing the Jim Crow regime of caste subjugation in the US South. Expressing ruling-class worries over whether these groups could or should assimilate into the predominant Anglo-Saxon pattern of the country, the term then referred to the intersection between the ethnic neighborhood and the slum, where segregation combined with physical disrepair and overcrowding to exacerbate urban ills such as criminality, family breakdown, and pauperism, and thwart participation in national life. This conception was given scientific authority by the ecological paradigm of the Chicago school of sociology. In his classic book *The Ghetto*, Louis Wirth (1928: p. 6) assimilates to the Jewish ghetto of medieval Europe the 'Little Sicilies, Little Polands, Chinatowns, and Black Belts in our large cities,' along with the 'vice areas' hosting deviant types such as hobos, bohemians, and prostitutes – all of which are said to be 'natural areas' born of the universal desire of different groups to 'preserve their peculiar cultural forms' and each fulfilling a specialized 'function' in the broader urban organism.

The notion contracted after World War II under the press of the Civil Rights movement to signify mainly the compact and congested enclaves to which African Americans were forcibly relegated as they migrated into the industrial centers of the North. The growth of a 'Black Metropolis in the womb of the white,' wherein Negroes evolved distinct and parallel institutions to compensate for and shield themselves from unflinching exclusion by whites (Drake and Cayton, 1945), contrasted sharply with the smooth residential dispersal of European Americans of foreign stock. Writing at the acme of the black uprisings of the 1960s, Kenneth Clark (1965: p. 11) made this relationship of ethnoracial subordination epicentral to his dissection of the *Dark Ghetto* and its woes: 'America has contributed to the concept of the ghetto the restriction of persons to a special area and the limiting of their freedom of choice on the basis of skin color. The dark

ghetto's invisible walls have been erected by the white society, by those who have power.' This diagnosis was confirmed by the Kerner Commission (1968: p. 2), a bipartisan taskforce appointed by President Johnson whose official report on the 'civil disorders' that rocked the American metropolis famously warned that, due to white racial intransigence, America was 'moving toward two societies, one black, one white – separate and unequal.' But over the ensuing two decades, the dark ghetto collapsed and devolved into a barren territory of dread and dissolution due to deindustrialization and state policies of welfare reduction and urban retrenchment. And, as racial domination grew more diffuse and diffracted through a class prism, the category was displaced by the duet formed by the geographic euphemism of 'inner city' and the neologism of 'underclass,' defined as the substratum of ghetto residents plagued by antisocial behaviors, acute joblessness, and social isolation (Wilson, 1987). By the 1990s, the neutralization of the 'ghetto' in policy-oriented research culminated in the expurgation of all mention of race and power to redefine it as any tract of extreme poverty, irrespective of population and institutional makeup, in effect dissolving the ghetto back into the slum.

The extension of the term to the study of the distinctive sociocultural patterns elaborated by homosexuals in the cities of advanced societies 'in response to both stigma and gay liberation' after the Stonewall riots (Levine, 1979: p. 31) and its recent resurgence in Western Europe in heated scientific and political debates over the links between postcolonial immigration, postindustrial economic restructuring, and urban dualization (Mingione, 1996) would seem only to further muddle its meaning. Yet one can extract out of these varied literatures common threads and recurrent properties to *construct a relational concept* of the ghetto as an *instrument of closure and control* that clears up most of the confusion surrounding it and makes it a powerful tool for the social analysis of ethnoracial domination and urban inequality. For this it suffices to return to the historical inception of the word and of the phenomenon it depicted in Renaissance Venice.

A Janus-Faced Institution of Ethnic Closure and Control

Coined by derivation from the Italian *giudecca*, *borghetto* or *gietto* (or from the German *gitter* or the Talmudic Hebrew *get:* the etymology is disputed), the word 'ghetto' initially refers to the forced consignment of Jews to special districts by the city's political and religious authorities. In medieval Europe, Jews were commonly allotted quarters wherein they resided, administered their own affairs, and followed their customs. Such quarters were granted or sold as a privilege to attract them into the towns and principalities for which they fulfilled key roles as money-lenders, tax collectors, and longdistance tradesmen. But, between the thirteenth and the sixteenth century, in the wake of the upheavals caused by the Crusades, favor gradually turned into compulsion (Stow, 1992). In 1516, the Senate of Venice ordered all Jews rounded up into the *ghetto nuovo*, an abandoned foundry on an isolated island enclosed by two high walls whose outer windows and doors were sealed while watchmen stood guard on its two bridges and patrolled the adjacent canals by boat. Jews were henceforth allowed out to pursue their occupations by day, but they had to wear a distinctive garb and return inside the gates before sunset on pain of serious punishment. These measures were designed as an alternative to expulsion to enable the city-state to reap the economic benefits brought by the presence of Jews (including rents, special taxes, and forced levies) while protecting their Christian residents from contaminating contact with bodies perceived as unclean and dangerously sensual, carriers of syphillis and vectors of heresy, in addition to bearing the taint of money-making through usury, which the Catholic Church equated with prostitution (Sennett, 1994: p. 224).

As this Venetian model spread in cities throughout Europe and around the Mediterranean rim (Johnson, 1987: pp. 235–245), territorial fixation and seclusion led, on the one hand, to overcrowding, housing deterioration, and impoverishment as well as excess morbidity and mortality, and, on the other, to institutional flowering and cultural consolidation as urban Jews responded to multiplying civic and occupational restrictions by knitting a dense web of group-specific organizations that served as so many instruments of collective succor and solidarity, from markets and business associations, to charity and mutual aid societies, to places of religious worship and scholarship. The *Judenstadt* of Prague, Europe's largest ghetto in the eighteenth century, even had its own city hall, the *Rathaus*, an emblem of the relative autonomy and communal strength of its residents, and its synagogues were entrusted not only with the spiritual stewardship but also with the administrative and judicial oversight of its population. Social life in the Jewish ghetto was turned inward and verged 'on overorganization' (Wirth, 1928: p. 62), so that it reinforced both integration within and isolation from without.

One can detect in this inaugural moment the four constituent elements of the ghetto, viz., *stigma, constraint, spatial confinement, and institutional encasement*. The ghetto is a social-organizational device that employs space to reconcile two antinomic purposes: to maximize the material profits extracted out of a group deemed defiled and defiling and to minimize intimate contact with its members so as to avert the threat of symbolic corrosion and contagion they carry. This same dual rationale of *economic exploitation cum social ostracization* governed the genesis, structure, and functioning of the African-American ghetto in the Fordist metropolis during most of the twentieth century. Blacks were recruited into northern US cities after World War I because their unskilled labor was indispensable to the industries that formed the backbone of the expanding factory economy. But there was no question of them mixing and consorting with whites, who regarded them as inherently vile, congenitally inferior, and shorn of ethnic honor owing to the stain of slavery. As blacks moved in from the South in millions, white hostility increased and patterns of discrimination and segregation that had hitherto been informal and inconsistent hardened in housing, schooling, and public accommodations and were extended to the economy and polity (Spear, 1968; Osofsky, 1971). African Americans had no choice but to seek refuge inside the bounded perimeter of the Black Belt and to endeavor to develop in it a network of separate institutions to procure the basic needs of the

castaway community. Thus arose a parallel city anchored by black churches and newspapers, black block clubs and lodges, black schools and businesses, and black political and civic associations, nested at the core of the white metropolis yet sealed from it by an impassable fence built of custom, legal suasion, economic discrimination (by realtors, banks, and the state), and by violence manifested in the beatings, fire-bombings, and riots that checked those who dared stray across the color line.

This forced institutional parallelism predicated on envelopping and inflexible spatial seclusion – not extreme poverty, housing blight, cultural difference, or mere residential separation – is what has distinguished African Americans from every other group in US history, as noted by leading students of the black urban experience from W.E.B. Du Bois and E. Franklin Frazier to Drake and Cayton to Kenneth Clark and Oliver Cox (Wacquant, 1998). It also characterizes the trajectory of the Burakumin in the Japanese city after the close of the Tokugawa era (Hane, 1982). As the descendants of the *eta*, the lowest of the four castes forming the estate order of feudal Japan, the Burakumin were untouchables in the eyes of the Buddhist and Shinto religions, and they were legally confined from sundown to sunup in out-of-the-way hamlets *(buraku)*, obliged to wear a yellow collar and to walk barefoot, expected to drop on their hands and knees when addressing commoners, and restricted to marrying solely among themselves. Though they were officially emancipated in 1871, as they moved into cities they were funneled against their will into notorious neighborhoods near garbage dumps, crematoria, jails, and slaughterhouses, widely viewed as nests of criminality and immorality. There, they were barred from industrial employment and locked in low-paying and dirty jobs, sent to separate schools, and compelled to remain endogamous by the indelible taint of their blood as traced through 'family registration records' (DeVos and Wagatsuma, 1966). In the late 1970s, according to the Burakumin Defense League, they were estimated to number 3 million, trapped in 6,000 ghettos in some thousand cities across the main island.

Spread over three continents and five centuries, the Jewish, African-American, and Burakumin cases demonstrate that the ghetto is not, *pace* Wirth (1928: pp. 284–285), a 'natural area' arising via environmental adaptation governed by a biotic logic 'akin to the competitive cooperation that underlies the plant community.' The error of the early Chicago school here consisted in falsely 'converting history into natural history' and passing ghettoization as 'a manifestation of human nature' virtually coterminous with 'the history of migration' (Wirth, 1928: p. 285) when it is a highly peculiar form of urbanization warped by asymmetric relations of power between ethnoracial groupings: a special form of *collective violence concretized in urban space*. That ghettoization is *not* an 'uncontrolled and undesigned' process, as Robert E. Park asserted in his preface to *The Ghetto* (Wirth, 1928: p. viii), was especially visible after World War II when the black American ghetto was reconstructed from the top down through state policies of public housing, urban renewal, and suburban economic development intended to bolster the rigid separation of blacks from whites (Hirsch, 1983). It is even more glaring in the instance of the 'caste cities' built by colonial powers to inscribe in space the hierarchical ethnic organization of their overseas possessions, such as Rabat under French rule over Morocco and Cape Town after the passage of the Group Areas Acts under the apartheid regime of South Africa (Abu-Lughod, 1980, Western, 1981).

Recognizing that it is a product and instrument of group power makes it possible to appreciate that, in its full-fledged form, the ghetto is a *Janus-faced institution* as it serves opposite functions for the two collectives that it binds in a relation of asymmetric dependency. For the dominant category, its rationale is to *confine and control*, which translates into what Max Weber calls the 'exclusionary closure' of the dominated category. For the latter, however, it is an *integrative and protective device* insofar as it relieves its members from constant contact with the dominant and fosters consociation and community building within the constricted sphere of intercourse that it creates. Enforced isolation from the outside leads to the intensification of social exchange and cultural sharing inside. Ghettos are the product of a mobile and tensionful dialectic of external hostility and internal affinity that expresses itself as ambivalence at the level of collective consciousness. Thus, although European Jews consistently protested relegation within their outcast districts, they were also deeply attached to them and appreciative of the relative security they afforded and the special forms of collective life they supported: Frankfurt's ghetto in the eighteenth century was 'not just the scene of confinement and persecution but a place where Jews were entirely, supremely, at home' (Gay, 1992: p. 67). Similarly, black Americans took pride in having 'erected a community in their own image,' even as they resented the fact that they had done so under duress, as a result of unyielding white exclusion aimed at warding off the specter of 'social equality,' that is, sexual mixing (Drake and Cayton, 1945: p. 115).

Disentangling Poverty, Segregation, and Ethnic Clustering

Articulating the concept of ghetto makes it possible to disentangle the relationship between ghettoization, urban poverty, and segregation, and thence to clarify the structural and functional differences between ghettos and ethnic neighborhoods. It also enables us to spotlight on the role of the ghetto as a symbolic incubator and matrix for the production of a spoiled identity.

1. *Poverty is a frequent but derivative and variable characteristic of ghettos:* the fact that most ghettos have historically been places of endemic and often acute misery owing to the paucity of space, the density of settlement, and the economic exploitation and generalized maltreatment of their residents does not imply that a ghetto is necessarily a place of destitution, nor that it is uniformly deprived. The *Judengasse* of Frankfurt, instituted in 1490 and abolished in 1811, went through periods of prosperity no less than penury and it contained patches of extraordinary opulence as court Jews helped the city become a vibrant center of trade and finance – part of its glamor to this day comes from it being the ancestral home of the Rothschild dynasty (Wirth, 1928: Chap. 4). James Weldon Johnson (1930: p. 4)

insisted that the Harlem of the 1930s was 'not a slum or a fringe' but the 'cultural capital' of black America, where 'the Negro's advantages and opportunities are greater than in any other place in the country.' Likewise, Chicago's 'Bronzeville' was far more prosperous at mid-century than southern black communities and harbored the largest and most affluent African-American bourgeoisie of its era (Drake and Cayton, 1945). Whether a ghetto is poor or not depends on extraneous factors such as demography, ecology, state policies, and the shape of the surrounding economy.

Conversely, not all dispossessed and dilapidated urban districts are ghettos. Declining white neighborhoods in the deindustrializing cities of the US Midwest and British Midlands, depressed rural towns of the former East Germany and southern Italy, and the disreputable *villas miserias* of the greater Buenos Aires at the close of the twentieth century are territories of working-class demotion and decomposition, not ethnic containers dedicated to maintaining an outcast group in a relationship of seclusive subordination. They are not ghettos other than in a metaphorical sense, no matter how impoverished – if extreme rates of poverty sufficed to make a ghetto, then large chunks of the former Soviet Union and most third-world cities would be gargantuan ghettos. The *favelas* of the Brazilian metropolis often portrayed as segregated dens of dereliction and disorganization turn out to be working-class wards with finely stratified webs of ties to industry and to the wealthy districts for which they supply household service labor. As in the *ranchos* of Venezuela and the *poblaciones* of Chile, the families that dwell in these squatter settlements span the color continuum and have extensive genealogical bonds to higher-income households; they are 'not socially and culturally marginal, but stigmatized and excluded from a closed class system' (Perlman, 1976: p. 195; also Quijano, 1968). Given that not all ghettos are poor and not all poor areas are ghettos, one cannot collapse and confound the analysis of ghettoization with the study of slums and lower-class districts in the city.

2. Similarly, *all ghettos are segregated but not all segregated areas are ghettos.* The select boroughs of the West of Paris, the exclusive upper-class suburbs of Boston or Berlin, and the 'gated communities' that have mushroomed in global cities such as São Paulo, Toronto, and Miami are monotonous in terms of wealth, income, occupation, and often ethnicity, but they are not for all that ghettos. Segregation in them is entirely voluntary and elective, and for that reason it is neither all-inclusive nor perpetual. Fortified enclaves of luxury package 'security, seclusion, social homogeneity, amenities, and services' to enable bourgeois families to escape what they perceive as 'the chaos, dirt, and danger of the city' (Caldeira, 2000: pp. 264–265). These islands of privilege serve to enhance, not curtail, the life chances and protect the life-styles of their residents, and they radiate a positive aura of distinction, not a sense of infamy and dread.

   This suggests that residential segregation is a necessary but not a sufficient condition for ghettoization. For a ghetto to emerge spatial confinement must, first, be imposed and all-encompassing and, second, it must be overlayed with a distinct and duplicative set of institutions enabling the group thus cloistered to reproduce itself within its assigned perimeter. If blacks are the only ethnic group to be 'hyper-segregated' in American society (Massey and Denton, 1992), it is because they are the only community to have combined involuntary segregation with organizational parallelism entrapping them in a separate and inferior social cosmos of their own, which in turn bolstered their residential isolation. That even involuntary segregation at the bottom of the urban order does not *eo ipso* produce ghettos is demonstrated by the fate of the declining French *banlieues* after the 1980s. Although they have been widely disparaged as 'ghettos' in public discourse and their inhabitants share a vivid feeling of being cast out in a 'penalized space' suffused with boredom, anguish, and despair (Pétonnet, 1982), relegation in these depressed concentrations of public housing at the urban periphery is based on class, not ethnicity; as a result they are culturally heterogeneous, typically harboring native French families along with immigrants from two dozen nationalities; and their inhabitants suffer not from institutional duplication but, on the contrary, from the lack of an ingrown organizational structure capable of sustaining them in the absence of gainful employment and adequate public services. Like the British or Dutch inner cities and the immigrant clusters of urban Germany or Italy, the French *banlieues* are, sociologically speaking, *anti-ghettos* (Wacquant to be published).

3. *Ghettos and ethnic neighborhoods have divergent structures and opposite functions:* moving beyond a gradational perspective to scrutinize the peculiar patterning of social relations within the ghetto as well as between it and the surrounding city throws into sharp relief the differences between the ghetto and the ethnic clusters or immigrant neighborhoods such as newcomers to the metropolis have formed in countless countries. The foreign 'colonies' of interwar Chicago that Robert Park, Ernest Burgess, and Louis Wirth – and after them the liberal tradition of assimilationist sociology and historiography – mistook for so many white 'ghettos' were scattered and mobile constellations born of cultural affinity and occupational concentration. Segregation in them was partial and porous, a product of immigrant solidarity and ethnic attraction instead of being imposed by outgroup hostility. Consequently, residential separation was neither uniformly nor rigidly visited upon these groups: in 1930, when the all-black Bronzeville harbored 92% of the city's Afro-American population, Chicago's Little Ireland was 'an ethnic hodge-podge' of 25 nationalities composed of only one-third Irish persons and containing a paltry 3% of the city's denizens of Irish ancestry (Philpott, 1978: pp. 141–145).

   What is more, the distinctive institutions of European immigrant enclaves were turned outward: they operated to facilitate adjustment to the novel environment of the US metropolis. They neither replicated the organizations of the country of origin nor perpetuated social isolation and cultural distinctiveness, and so they typically waned within two generations as their users gained access to their American counterparts and climbed up the class order and the corresponding ladder of places (Nelli, 1970; a similar process of spatial diffusion via class incorporation of Belgian, Italian,

Polish, and Iberian immigrants in the French industrial city is reported by Noiriel, 1988), all of which is in sharp contrast with the immutable racial exclusivity and enduring institutional alterity of the Black Belt. This Chicago illustration dramatizes the fact that immigrant neighborhood and ghetto serve diametrically opposed functions: one is a springboard for *assimilation* via cultural learning and social-cum-spatial mobility, and the other a material and symbolic isolation ward geared toward *dissimilation*. The former is best figured by a bridge, and the latter by a wall.

A Tainted Identity Machine

The ghetto is not only the concrete means and materialization of ethnoracial domination through the spatial segmentation of the city but also a potent *collective identity machine* in its own right, for it helps incrustate and elaborate the very division of which it is the expression in two complementary and mutually reinforcing ways. First, the ghetto sharpens the boundary between the outcast category and the surrounding population by deepening the sociocultural chasm between them: it renders its residents objectively and subjectively more dissimilar from other urban dwellers by submitting them to unique conditionings, so that the patterns of cognition and conduct they fashion have every chance of being perceived by outsiders as singular, exotic, even aberrant (Sennett, 1994: p. 244; Wilson, 1987: pp. 7–8), which feeds prejudicial beliefs about them. Second, the ghetto is a cultural combustion engine that melts divisions among the confined group and fuels its collective pride even as it entrenches the stigma that hovers over it. Spatial and institutional entrapment deflect class differences and corrode cultural distinctions within the relegated ethnoracial category. Thus Christian ostracism welded Ashkenazic and Sephardic Jews under an overarching Jewish identity such that they evolved a common 'social type' and 'state of mind' across the ghettos of Europe (Wirth, 1928: pp. 71–88, 1964). America's dark ghetto similarly accelerated the sociosymbolic amalgamation of mulattos and Negroes into a single 'race' and turned racial consciousness into a mass phenomenon fueling community mobilization against continued caste exclusion (Drake and Cayton, 1945: p. 390).

Yet this unified identity cannot but be stamped with ambivalence as it remains tainted by the very fact that ghettoization proclaims what Weber calls the 'negative evaluation of honor' assigned to the group confined. It is therefore wont to foster among its members sentiments of self-doubt and self-hatred, dissimulation of one's origin through 'passing,' the pernicious derogation of one's kind, and even fantasical identification with the dominant (Clark, 1965: pp. 63–67). And, because ghettoization is typically bound up tightly with ethnicity, segregation, and poverty, it is difficult to discern empirically which of the properties exhibited by ghetto dwellers are 'ghetto-specific cultural traits' as opposed to properties expressive of class, community, or masculinity (Hannerz, 1969: p. 79). Also, cultural forms forged in the ghetto seep across its boundaries and circulate through the surrounding society where they often become outward signs of cultural rebelliousness and social eccentricity – as indicated by the fascination of bourgeois teenagers around the world for black American 'gangster rap.' This makes it difficult to distinguish between cultural forms effectively in currency among ghetto residents and the public imagery of them diffused in the broader society (including via scholarly writings).

It is fruitful to think of ghetto and ethnic cluster as *two ideal typical configurations situated at opposite ends* of a continuum along which different groups can be located or travel over time depending on the intensity with which the forces of stigma, constraint, spatial confinement, and institutional duplication and completeness coalesce with each other and impinge upon them. Ghettoization can then be turned into a *multilevel variable* for comparative analysis and empirical specification. It can become attenuated to the point where, through gradual erosion of its spatial, social, and mental boundaries, the ghetto devolves into an elective ethnic concentration operating as a springboard for structural integration and/or cultural assimilation into the broader social formation. This describes well the trajectory of the Chinatowns of the United States from the early to the late twentieth century (Zhou, 1992) and the status of the Cuban immigrant enclave of Miami that fostered integration through biculturalism after the Mariel exodus of 1980 (Portes and Stepick, 1993). It also characterizes the 'Kimchee Towns' in which Koreans have converged in the metropolitan areas of Japan, which sport a blend of features making them a hybrid between ghetto and ethnic cluster (DeVos and Chung, 1981): they are places of infamy that first arose through enmity and constraint, but over the years their population has become ethnically mixed and they have enabled Koreans to socialize and intermarry with Japanese neighbors as well as obtain Japanese citizenship through naturalization. This schema also fits the so-called gay ghetto, which is more aptly characterized as a 'quasi-ethnic community' since 'most gay persons can "pass" and need not be confined to interacting with their "own kind" and none are forced to reside in the areas of visible concentration of gay institutions (Murray, 1979: p. 169).

The double-sidedness of the ghetto as a weapon and shield implies that, to the degree that its institutional completeness and autonomy are abridged, its protective role for the subordinate group is diminished and risks being swamped by its exclusionary modality. In cases where its residents cease to be of economic value to the dominant group, ethnoracial encapsulation can escalate to the point where the ghetto serves as an apparatus merely to warehouse the spoiled group or to prepare it for the ultimate form of ostracization, i.e., physical annihilation. The first scenario fits the evolution of the black American 'hyperghetto' in the post-Civil Rights era: having lost its function of reservoir of unskilled labor power, it has become symbolically linked to the hypertrophied carceral system of the United States by a triple relationship of structural homology, functional surrogacy, and cultural fusion (Wacquant, 2004). The second scenario is that implemented by Nazi Germany, which revived the *Judenghetto* between 1939 and 1944, first, to impoverish and concentrate Jews with a view toward relocation and later, when mass deportation turned out to be impractical, to funnel them toward extermination camps (Friedman, 1980, Browning 1986).

The unchecked intensification of its exclusionary thrust suggests that the ghetto might be most profitably studied not by analogy with urban slums, lower-class neighborhoods, and immigrant enclaves but alongside the reservation, the refugee camp, and the prison, as belonging to a broader class of institutions for the forced confinement of dispossessed and dishonored groups. It is not by happenstance that the Bridewell of London (1555), the *Zuchthaus* of Amsterdam (1654), and the *Hospital general* of Paris (1656), designed to instill the discipline of wage work to able-bodied vagrants, beggars, and criminals via incarceration, were invented around the same time as the Jewish ghetto. And that today's sprawling refugee camps in Rwanda, Sri Lanka, and in the occupied territories of Palestine look ever more like a cross between the ghettos of late medieval Europe and gigantic gulags.

Gibson's Theory of Perceptual Learning

Abstract

This article describes the key ideas of the influential psychologist Eleanor J. Gibson, developed over 70 years of research with infants, children, adults, and a wide range of nonhuman species. Gibson's ecological approach to perceptual learning and development describes how perception – extracting meaningful information from the environment to guide actions adaptively – improves with experience, the acquisition of new means of exploration, and the development of new perception–action systems.

Learning to Perceive or Perceiving to Learn?

Eleanor Jack Gibson built her theory of perceptual learning over a 70-year research career. She published her first paper on perceptual learning in 1932 (Gibson et al., 1932) and her last book in 2002 (Gibson, 2002). There is a clear thread from beginning to end, but she was not dogmatic in her ideas; her theories were always informed by data, and data collection was often inspired by real life and serendipity. Her theory is consistent with but not identical to James Gibson's (1979) ecological approach to perception. Although the Gibsons were married and shared many arguments and ideas about perceptual learning and development, they wrote only five articles together (Gibson, 2002). Thus, in this article, 'Gibson' refers to Eleanor Gibson unless otherwise noted. Gibson's 1969 book, *Principles of Perceptual Learning and Development*, described her theory in detail and jump-started a new field of inquiry. However, as new methods and findings became available, notably new ways of studying perception in young infants, Gibson questioned things that she had once taken for granted and broadened her domain of inquiry. In later writings, Gibson critiqued her 1969 account for failing to capture how infants learn to detect the perceptual information for guiding action adaptively as their perceptual-motor systems are developing. In fact, she considered infancy to be the perfect place to study perceptual learning (Gibson, 1992) and she was instrumental in building the field of infant perception (Pick, 1992).
